Late benign syphilis is another now uncommon form of tertiary syphilis. It results from the chronic inflammatory response to *T. pallidum* and the formation of a granulomatous type of lesion called a *gumma*. Gummas may be ulcerative, nodular, or noduloulcerative and most commonly occur in the skin and bones but may also invade the viscera, muscles, and other structures.

SYPHILIS IN PERSONS WITH HIV INFECTION

Because syphilis and human immunodeficiency virus (HIV) infection share means of transmission and other risk factors, both infections often coexist. Moreover, syphilis, like other genital ulcer diseases, facilitates HIV transmission. Clinical observation and case reports suggest that HIV-infected patients may experience a more aggressive course of syphilis, with more frequent occurrence of neurosyphilis especially in the early stages of infection. Occasional unusual serologic reactions can occur in HIV-infected patients including very high or fluctuating non-treponemal antibody titers; false-positive non-treponemal tests and false-negative treponemal tests have also been documented. Nevertheless, available data suggest that HIV infection does not significantly change the presentation, clinical course, or response to treatment of syphilis.

SYPHILIS IN PREGNANCY

The clinical manifestations of syphilis are not altered in pregnancy; however, syphilis has widespread complications for both the infected mother and the fetus. Adverse pregnancy outcomes include early fetal loss, preterm delivery, low birth weight, and congenital syphilis in the neonate.

Laboratory tests

DIRECT EXAMINATION

Direct microscopic examination can provide immediate diagnosis of primary and secondary syphilis. Dark-field microscopy must be used because *T. pallidum's* narrow width (0.15 μm) renders the organism below the level of resolution of light microscopy. Wet preparations can be made from the skin or mucous membrane lesions of primary or secondary syphilis. Examination reveals tightly coiled organisms 6 to 14 μm long and 0.25 to 0.30 μm wide, with corkscrew motility. When examination of specimens must be delayed or oral lesions evaluated, direct fluorescent antibody testing can be useful. This test specifically detects *T. pallidum* and eliminates confusion with oral treponemal saprophytes whose morphology is similar to that of *T. pallidum*. Polymerase chain reaction (PCR) assays for diagnosis of syphilitic lesions have been developed and used in research studies; however, none are yet commercially available.

SEROLOGIC TESTS

Serologic tests for syphilis measure either nonspecific non-treponemal antibody or specific treponemal antibody. Non-treponemal antibody tests measure immunoglobulin G (IgG) and immunoglobulin M (IgM) to lipoidal material released from damaged host cells as well as to lipoprotein-like material and cardiolipin released by the treponemes. Non-treponemal antibody titers generally correlate with disease activity; titers fall progressively over time and are expected to decrease 4-fold in response to therapy. The following non-treponemal tests are commonly used: VDRL test, rapid plasma reagin (RPR), the toluidine red unheated serum test (TRUST), and the unheated serum reagin test (USR). Biologic false-positive non-treponemal test results occur in 1% to 2% of the general population, and are associated with several conditions including viral infections, pregnancy, malignancy, autoimmune diseases, and advanced age. False-negative results can occur from the prozone phenomenon in which patients with high non-treponemal titers can have weak or negative results at low dilutions due to excess antibody, although this is rare.

Specific treponemal antibody tests are needed to confirm a current or past diagnosis of syphilis. These tests detect antibodies formed in response to treponemal antigens. Treponemal tests usually

remain reactive after treatment, but a small proportion of infected persons can become seronegative. Commonly used treponemal tests include the fluorescent antibody absorption (FTA-ABS), microhemagglutination assay for *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination (TP-PA) test for syphilis.

Several new automated treponemal enzyme immunoassays (EIAs), chemiluminescence immunoassays, and immunoblots for *T. pallidum* that detect treponemal IgM and/or IgG have been US Food and Drug Administration (FDA) approved as screening and confirmatory tests for syphilis diagnosis. The majority of the newer assays use recombinant *T. pallidum* antigens to detect treponemal antibodies from patient specimens. Rapid, point-of-care tests which can provide results within 20 minutes have also been developed primarily for detection of treponemal antibodies; one of the rapid tests has received FDA approval and may be useful in settings with limited laboratory capabilities.

Traditionally, non-treponemal tests are used for screening followed by a treponemal test for confirmation. However, with the development of automated EIAs, some larger laboratories are using a reverse screening algorithm for syphilis testing. In the reverse algorithm, a positive treponemal test result is followed by a non-treponemal test to determine active infection. If the non-treponemal test is negative, then a second treponemal assay is recommended to confirm the results of the initial treponemal test. An individual with a positive treponemal test but negative non-treponemal titer may have early syphilis, late latent syphilis, past treated syphilis, or a false-positive treponemal test. Therefore, obtaining a thorough patient history to determine risks for recent exposures or past infections is critical to determining patient management. Treatment is usually indicated for persons with positive treponemal tests and non-reactive non-treponemal tests, unless a history of treatment exists.

CSF EVALUATION

CSF should be examined in all syphilis patients with neurologic signs or symptoms (e.g., acute or chronic meningitis, ophthalmic or auditory symptoms, cranial nerve palsies, motor or sensory deficits, cognitive dysfunction), evidence of active tertiary syphilis, and in those with probable treatment failure, especially among HIV-infected persons. Performance of lumbar puncture among asymptomatic HIV-infected patients is controversial, but may be considered among coinfected persons with a non-treponemal titer $\geq$1:32 and CD4 count of $\leq$350 cells/mm^3.

When CSF specimens are free of blood contamination, a positive CSF VDRL test confirms the diagnosis of neurosyphilis. However, the sensitivity of the CSF VDRL is limited and a negative test does not rule out neurosyphilis, especially in the presence of CSF pleocytosis and increased CSF protein levels. The CSF FTA-ABS is more sensitive than the CSF VDRL, but false-positive results have been reported.

Treatment and follow-up

Treatment and follow-up are outlined in Tables 163.1 and 163.2 for HIV-uninfected and HIV-infected adults. Penicillin is the drug of choice for all stages of syphilis infection. Alternative treatment regimens are available for patients with penicillin allergies, but there are limited data on efficacy. Therefore, pregnant women who are allergic to penicillin should be desensitized and treated with penicillin. HIV-positive patients with syphilis should be treated with penicillin if at all possible. Azithromycin 2 g orally in a single dose results in similar cure rates as benzathine penicillin in HIV-uninfected patients with early syphilis; however, its routine use is not recommended due to widespread resistance of *T. pallidum* to macrolides.

Clinical and serologic follow-up of patients after syphilis treatment is essential due to the potential for treatment failure. For HIV-negative persons, repeat evaluation should be performed at 6 and 12 months after therapy for early syphilis, and at 6, 12, and 24 months for latent syphilis. For pregnant women, serologic titers should be repeated at 28–32 weeks' gestation and at delivery as recommended for the disease stage. Although non-treponemal titers may fall more slowly among HIV-positive patients than in individuals who are HIV negative after treatment, more frequent follow-up in HIV-infected patients is recommended (see Table 163.2) due to the potential for treatment failure. Vigilant follow-up for patients coinfected with HIV is important to document resolution of infection or to prompt immediate evaluation if relapse, reinfection, or other complications occur.

Serologic response to therapy is demonstrated by at least a 4-fold decrease in non-treponemal titers from baseline (two dilution decrease, i.e.,

Table 163.1 Management of syphilis in adults including pregnant women without known HIV infection

Primary, secondary, or early latent syphilis (duration ≤1 yr)

Treatment

- Benzathine penicillin G, 2.4 million U IM once
- If penicillin allergy:[a]
  - Doxycycline 100 mg PO BID for 2 wk *or* tetracycline 500 mg PO QID for 2 wk
  - Ceftriaxone 1 g IM *or* IV for 10–14 d (caution: some patients with penicillin allergy are also allergic to ceftriaxone)

Treatment (for pregnant women)

- Benzathine penicillin G, 2.4 million U IM once (if penicillin allergic, patients should be desensitized and treated with penicillin); some experts follow with benzathine penicillin G, 2.4 million U IM administered 1 wk after the initial dose

Management and follow-up

- HIV testing
- If evidence of neurologic or ophthalmic disease, evaluate for neurosyphilis and do slit-lamp examination
- Repeat serology and clinical examination at 6 and 12 mo for HIV-negative persons
- Repeat serology at 28–32 weeks' gestation and at delivery for pregnant women
- If symptoms persist or recur, or if 4-fold increase in RPR or VDRL titer occurs, consider treatment failure or reinfection. Repeat HIV testing, consider LP, and retreat
- If RPR or VDRL titers do not fall 4-fold within 6–12 mo of treatment, conduct additional clinical and serologic follow-up

Late latent syphilis or syphilis of unknown duration

Treatment

- Benzathine penicillin G, 2.4 million U IM every wk, for 3 wk
- If penicillin allergy:[a]
  - Doxycycline, 100 mg PO BID for 4 wk or tetracycline, 500 mg PO QID for 4 wk

Treatment (for pregnant women)

- Benzathine penicillin G, 2.4 million U IM every wk for 3 wk (if penicillin allergic, patients should be desensitized and treated with penicillin)

Management and follow-up

- HIV testing
- Examine CSF before treatment if any of the following are present:
  - Neurologic or ophthalmic signs or symptoms
  - Evidence of active tertiary syphilis (e.g., aortitis or gumma)
  - Treatment failure
- Repeat quantitative VDRL or RPR at 6, 12, and 24 mo. Repeat serology at 28–32 weeks' gestation and at delivery for pregnant women
  - Patients with a normal CSF examination should be retreated for latent syphilis if:
    - Serologic titers increase 4-fold or
    - An initially high titer (≥1:32) fails to fall at least 4-fold within 12–24 mo or
    - Patient develops signs or symptoms consistent with syphilis

Tertiary syphilis (gumma or cardiovascular syphilis without neurosyphilis)

Treatment

- Benzathine penicillin G, 2.4 million U IM weekly for 3 wk
- If penicillin allergy, use treatment for late latent syphilis[a]

Treatment (for pregnant women)

- Benzathine penicillin G, 2.4 million U IM every wk for 3 wk (if penicillin allergic, patients should be desensitized and treated with penicillin)

Management

- HIV testing
- Examine CSF

Neurosyphilis

Treatment

- Aqueous crystalline penicillin G, 3 million to 4 million U IV q4h for 10–14 d; some experts follow with benzathine penicillin G, 2.4 million U IM weekly for 3 wk
- Alternative (if compliance is certain):
  - Procaine penicillin, 2.4 million U IM every day for 10–14 d, plus probenecid, 500 mg PO QID for 10–14 d; some experts follow with benzathine penicillin G, 2.4 million U IM weekly for 3 wk

Management

- HIV testing
- Repeat CSF examination every 6 mo until CSF cell count is normal
- Consider retreatment if cell count has not decreased after 6 mo or if CSF is not normal after 2 yr

Abbreviations: HIV = human immunodeficiency virus; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory test; LP = lumbar puncture; CSF = cerebrospinal fluid.

[a] HIV-infected, penicillin-allergic patients who receive alternative therapies should be closely monitored. If compliance cannot be ensured, patients should be desensitized and treated with penicillin.

Table 163.2 Treatment of HIV-positive patients with syphilis

Primary and secondary syphilis

Treatment

- Benzathine penicillin G, 2.4 million U IM once
- If penicillin allergy: manage according to recommendations for HIV-negative patients with primary and secondary syphilis (see Table 163.1)

Management

- Clinical and serologic evaluation 3, 6, 9, 12, and 24 mo after therapy
- Examine CSF if RPR or VDRL titers fail to show a 4-fold decrease within 6–12 mo or there is other evidence of treatment failure
  - If CSF normal, retreat with penicillin G, 2.4 million U IM weekly × 3 wk
  - If CSF suggests neurosyphilis, treat for neurosyphilis as in Table 163.1

Early latent syphilis

Manage and treat according to recommendations for HIV-negative patients with primary and secondary syphilis (see Table 163.1). Patients with penicillin allergy whose compliance with therapy or follow-up cannot be ensured should be desensitized and treated with penicillin

Late latent syphilis or latent syphilis of unknown duration

Treatment and management

- Consider CSF examination
  - If CSF normal, give benzathine penicillin G, 2.4 million U IM weekly × 3 wk
    - If penicillin allergy: manage according to recommendations for HIV-negative patients with late latent syphilis or latent syphilis of unknown duration. However, patients with penicillin allergy whose compliance with therapy or follow-up cannot be ensured should be desensitized and treated with penicillin
  - If CSF suggests neurosyphilis, treat for neurosyphilis as in Table 163.1

Management

- Clinical and serologic evaluation 6, 12, 18, and 24 mo after therapy
- Examine CSF and retreat accordingly if:
  - Clinical symptoms develop or RPR or VDRL titers rise 4-fold at any time or RPR or VDRL titer fails to fall 4-fold between 12 and 24 mo

Neurosyphilis

Treatment and management as in Table 163.1

Abbreviations: CSF = cerebrospinal fluid; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory test; HIV = human immunodeficiency virus.

from 1:64 to 1:16) or seroreversion to a nonreactive non-treponemal test. However, despite appropriate treatment, approximately 20% of patients with early syphilis may remain serofast (indicated by a less than 4-fold decline in non-treponemal titers or persistent low-level titers over time). Serofast patients may warrant subsequent clinical and serologic monitoring; however, whether they need to receive retreatment remains unclear. Patients who have evidence of treatment failure based on recurrent signs or symptoms, or a sustained 4-fold increase in non-treponemal titers should undergo HIV testing and CSF examination, especially when there are symptoms suggestive of neurosyphilis.

For patients with neurosyphilis and evidence of CSF pleocytosis, follow-up CSF examination should be repeated every 6 months after treatment. The CSF white cell count should decrease within 6 months; this may occur more slowly in HIV-infected patients than in HIV-negative persons. Regardless of HIV status, retreatment should be considered if the CSF cell count has not decreased after 6 months or if the CSF parameters do not normalize 2 years after therapy.

NONVENEREAL TREPONEMATOSES

Yaws, pinta, and bejel (endemic syphilis) are caused respectively by *T. pallidum* subsp. *pertenue; Treponema carateum*; and *T. pallidum* subsp. *endemicum*. These diseases, seen mainly in tropical and subtropical regions, are transmitted by direct contact with infected skin lesions and not primarily by sexual contact. Like venereal syphilis, these diseases have self-limited primary and secondary stages, a latent stage, and a late stage with destructive lesions. The causative agents are morphologically indistinguishable from *T. pallidum* subsp. *pallidum*, and the serologic responses they elicit are identical to those of venereal syphilis. Diagnosis can be made by dark-field examination of lesions or serologic testing. Long-acting penicillin G, the treatment of choice, has dramatically decreased the incidence of these diseases in endemic regions.

Yaws occurs in the tropical regions of Africa, Southeast Asia, South America, and Oceania. About 3 to 5 weeks after infection, papules develop, which enlarge, erode, and then spontaneously heal. A generalized secondary eruption of similar lesions occurs weeks to months later,

sometimes associated with osteitis or periostitis. In the late stage, infected persons may develop hyperkeratoses on the palms and soles; plaques, nodules, and ulcers of the skin; and gummatous bone lesions.

Pinta occurs in remote parts of Mexico, Central America, and Colombia. About 7 to 21 days after infection, small, red, pruritic papules develop, which enlarge, become squamous, and merge with other primary lesions. These lesions eventually heal, but residual hypopigmentation persists. Three to 12 months after the appearance of the primary lesions, small scaly papules known as *pintids* appear. These may eventually become brown, gray, or blue and may recur as long as 10 years after initial infection. Depigmented lesions develop in the late stage.

Bejel occurs in Africa and western Asia. Unlike yaws and pinta, bejel is spread not only by direct contact but also by eating and drinking utensils. Primary lesions are seldom seen. Secondary manifestations include mucous patches, condylomata lata, split papules at the angles of the mouth, and lymphadenopathy. Gummatous lesions of the skin, nasopharynx, and bones are common in the late stage.

164. Lyme disease

Janine Evans

Lyme disease, a systemic illness caused by the spirochete *Borrelia burgdorferi*, is the most common tick-borne disease in the United States. In 2011, 48 states reported 24 364 cases of Lyme disease using the Council of State and Territorial Epidemiologists (CTSE)/Centers for Disease Control and Prevention (CDC) surveillance case definition. Since the original discovery of Lyme arthritis in the mid 1970s the clinical spectrum of Lyme disease has expanded to include a wide variety of organ systems, primarily the skin, joints, nervous system, and heart. Protean symptoms, uncertainty in diagnosis due to lack of definitive testing methods, and public fear of late sequelae of disease often lead to overdiagnosis and overtreatment. Although optimal therapy of some of the clinical features of Lyme disease is unclear, better understanding of the natural history, epidemiology, and pathogenesis of Lyme disease helps in the often confusing and difficult decisions related to diagnosis and treatment.

B. burgdorferi has been isolated from blood, skin, cerebrospinal fluid (CSF) specimens, and (rarely) other specimens from infected patients although, with the exception of skin biopsy specimens, culture of *B. burgdorferi* from sites of infection is a low-yield procedure. *B. burgdorferi* displays phenotypic and genotypic diversity and has been classified into separate genospecies, five of which are pathogenic to humans: *Borrelia burgdorferi sensu stricto*, which includes all strains studied thus far from the United States and some European and Asian strains, and *Borrelia garinii*, *Borrelia afzelii, Borrelia spielmanii*, and *Borrelia bavariensis*, which are found in Europe and Asia. *B. afzelii* seems primarily associated with a chronic skin lesion, acrodermatitis chronica atrophicans, rare in the United States, and *B. garinii* is predominant among CSF isolates.

Lyme disease occurs in three principal foci in the United States: the Northeast, the upper Midwest, and the Pacific Coast. These areas correspond to the distribution of the predominant tick vectors of Lyme disease in the United States, *Ixodes scapularis* in the East and Midwest, and *Ixodes pacificus* in northern California. Lyme disease also occurs widely in Europe, where it is transmitted by the sheep tick, *Ixodes ricinus*, and *Ixodes persulcatus*, the taiga tick. The latter is distributed throughout eastern Europe and Asia.

The largest number of reported cases of Lyme disease in Europe are from Germany, Austria, Slovenia, Sweden, the Czech Republic, and the Baltic states. *I scapularis* have a 3-stage, 2-year life cycle. Transovarial passage of *B. burgdorferi* occurs at a low rate. Ticks become infected with spirochetes by feeding upon a spirochetemic animal, typically small mammals, during larval and nymphal stages. In highly endemic areas from 20% to more than 60% of *I. scapularis* carry *B. burgdorferi*. Humans are only an incidental host of the tick; contact is typically made in areas of underbrush or high grasses, but may occur in well-mown lawns in endemic areas. Lyme disease occurs most commonly during April through July when nymphal *I. scapularis* feed. Animal models show that transmission is unlikely to occur before a minimum of 36 hours of tick attachment and feeding.

CLINICAL MANIFESTATIONS

Clinical features of Lyme disease are typically divided into three general stages termed early localized, early disseminated, and late persistent infection. These stages may overlap, and most patients do not exhibit all stages. Direct invasion of the organism with a resultant vigorous inflammatory reaction has been demonstrated to be responsible for many of the clinical manifestations associated with Lyme disease, so the manifestations respond to antibiotic therapy. Some features, such as late neurologic deficits and chronic arthritis, may respond poorly to treatment. It is not absolutely clear that live organisms are responsible for these later symptoms.

Figure 164.1 Classic erythema migrans lesion.

Seroconversion can occur in asymptomatic individuals, but is rare with strict surveillance.

Early localized disease

Erythema migrans (EM), the hallmark of Lyme disease, begins at the site of a deer tick bite after 3 to 32 days (Figures 164.1 and 164.2). It is reported by 60% to 80% of patients, appearing as a centrifugally expanding erythematous macule or papule, often with central clearing. The thigh, groin, and axilla are common sites. The lesion may be warm, pruritic, and painful, but is often asymptomatic and easily missed if out of sight. Occasionally, these lesions may develop blistering or scabbing in the center, remain an even, intense red without clearing, or develop a bluish discoloration. Spirochetes are present in the EM lesion and can be readily cultured from the expanding edge. Mild musculoskeletal flu-like symptoms such as a low-grade fever, chills, malaise, headache, fatigue, arthralgias, and myalgias may accompany EM lesions. Theoretically such symptoms can occur without dissemination of the organism, via local generation of cytokines. Untreated EM resolves after several weeks and treated lesions clear within several days.

Figure 164.2. Erythema migrans lesion.

Early disseminated

In some patients the spirochete disseminates hematogenously to multiple sites causing characteristic clinical features. Secondary annular lesions, sites of metastatic foci of *Borrelia* in the skin, develop within days of onset of EM in about half of US patients. They are similar in appearance to EM, but are generally smaller, migrate

less, and lack indurated centers. In addition to musculoskeletal flu-like symptoms, mild hepatitis, splenomegaly, sore throat, nonproductive cough, testicular swelling, conjunctivitis, and regional and generalized lymphadenopathy may sometimes occur during early stages.

Diagnosis of early localized and early disseminated Lyme disease is based on clinical presentation, because serologic confirmation is often lacking and culture is not readily available. EM is diagnostic of Lyme disease although atypical lesions and rashes mimicking EM may be confusing. A history of a tick bite and residence or travel in an endemic area should be sought in patients presenting with rashes compatible with EM or a flu-like illness in summer. Specific immunoglobulin (Ig)M antibody responses against *B. burgdorferi* develop 2 to 6 weeks after the onset of EM. Immunoglobulin (Ig)G antibody levels appear approximately 6 weeks after disease onset but may not peak until months or even years into the illness. The highest titers occur during arthritis. Antibodies are typically detected using indirect immunofluorescence, enzyme-linked immunosorbant assay (ELISA), and immunoblotting (Western blot). Antibody responses may persist for months to years after successful eradication of infection. Two-tier testing is recommended, with ELISA screening done first and if positive an immunoblot performed.

Late disease

Late manifestations of Lyme disease typically occur months to years after the initial infection. In the United States, arthritis is the dominant feature of late Lyme disease, reported in approximately 60% of untreated individuals. Less often, individuals develop late chronic neurologic disease. Another late finding (years) associated with this infection is a chronic skin lesion, acrodermatitis chronica atrophicans, well known in Europe but rare in the United States. These late manifestations are discussed below.

THERAPY

Early Lyme disease

The symptoms of early Lyme disease resolve spontaneously in most cases; therefore, the goals of therapy for early localized and mild early disseminated Lyme disease are to shorten the duration of symptoms and reduce the risk of developing serious late manifestations of infection. Treatment of these stages with oral antibiotics is adequate in the majority of patients (see Table 164.1). In patients with acute disseminated Lyme disease but without meningitis, oral doxycycline appears to be equally effective as parenteral ceftriaxone in preventing the late manifestations of disease. Initial studies of treatment for early Lyme disease reported therapy with phenoxymethyl penicillin, erythromycin, and tetracycline, in doses of 250 mg four times a day for 10 to 20 days, shortened the duration of symptoms of early Lyme disease. Phenoxymethyl penicillin and tetracycline were superior to erythromycin in preventing serious late manifestations of disease. Subsequent clinical trials have proven amoxicillin and doxycycline to be equally efficacious. Amoxicillin has largely replaced use of penicillin because of greater in vitro activity against *B. burgdorferi*. It is the preferred antibiotic choice in children under the age of 8 years. Concomitant use of probenecid has not been definitively shown to improve clinical outcome and is associated with a higher incidence of side effects. Doxycycline is usually selected over tetracycline because of its twice-daily dose schedule, increased gastrointestinal absorption and tolerability, and greater central nervous system (CNS) penetration. Doxycycline is effective in treating *Anaplasma phagocytophilum* (formerly known as *Ehrlichia phagocytophila*), an organism also transmitted by *I. scapularis* ticks; amoxicillin is not. Cefuroxime axetil, an oral second-generation cephalosporin, has been shown to be about as effective as amoxicillin and doxycycline in treating early Lyme disease; azithromycin, an azilide analog of erythromycin, somewhat less so. Macrolide antibiotics are not recommended as first-line therapy for early Lyme disease. Long-term follow-up of patients treated during early stages of Lyme disease support the current dosing regimens. Patients who received a 14- to 21-day course of a recommended antibiotic rarely developed late manifestations of illness. Recent studies have indicated that a 10-day course of doxycycline is adequate therapy for EM. Jarisch–Herxheimer-like reactions, an increased discomfort in skin lesions and temperature elevation occurring within hours after the start of antibiotic treatment, have been encountered in 14% of patients treated for early Lyme disease. They typically occur within 2 to 4 hours of starting therapy, are more common in severe disease, and are presumably due to rapid killing of a large number of spirochetes.

Minor symptoms including arthralgia, fatigue, headaches, and transient facial palsy

Table 164.1 Treatment guidelines

Antibiotic regimen	Comments
Erythema migrans	
Amoxicillin, 500 mg 3 times daily for 14–21 d	Pediatric dose is 25–50 mg/kg/d three times daily
Doxycycline (Vibramycin), 100 mg twice daily for 10–21 d	Also effective against *Anaplasma phagocytophium*; not recommended for children under 8 years of age, pregnant or lactating women
Cefuroxime axetil (Ceftin), 500 mg twice daily for 14–21 d	Pediatric dose 30 mg/kg/d twice daily
Azithromycin (Zithromax), 500 mg daily for 7–10 d	Not recommended as first-line therapy; less effective than other regimens
Early disseminated disease (without neurologic, cardiac, or joint involvement)	
Initial treatment is the same as for erythema migrans except duration of treatment may be extended to 21–28 d	
Neuroborreliosis	
Isolated seventh nerve palsy	
Initial treatment is the same as for erythema migrans except duration of treatment is 21–28 d. The need for cerebrospinal fluid examination remains controversial	
All other neurologic manifestations (including meningitis, radiculoneuritis, peripheral neuropathy, encephalomyelitis, chronic encephalopathy)	
Ceftriaxone (Rocephin), 2 g daily for 14–30 d	30-d regimen associated with fewer relapses in patients with chronic encephalopathy
Penicillin G, 20 million units daily for 14–28 d	Pediatric dose 200 000–400 000 units/kg/d every 4 h
Cefotaxime sodium (Claforan), 2 g every 8 h	Pediatric dose 150–200 mg/kg/d in 3–4 divided doses for 14–28 d
Doxycycline, 100 mg twice daily (oral or intravenous) for 14–28 d	No published experience in the United States
Carditis	
Doxycycline, 100 mg orally twice daily for 21 d	For first degree heart block, PR interval <0.3 s
Amoxicillin, 500 mg three times daily for 21 d	For first degree heart block, PR interval <0.3 s
Ceftriaxone, 2 g daily for 14–21 d	Optimal duration of therapy is unknown
Penicillin G, 20 million units daily for 14–30 d	Optimal duration of therapy is unknown, given in divided doses every 4 h
Arthritis	
Amoxicillin 500 mg four times daily for 30–60 d	Oral regimens should be limited to patients without evidence of neurologic involvement. Oral treatment may be extended for 60 d if no response to 30-d course
Doxycycline 100 mg two times daily for 30–60 d	
Cefuroxime axetil, 500 mg twice daily for 30–60 d	For patients with doxycycline and penicillin allergy
Ceftriaxone, 2 g daily for 14–30 d	
Lyme disease in pregnancy	
Amoxicillin, 500 mg three times daily for 21 d	For early localized disease only
Ceftriaxone, 2 g daily for 14–28 d	
Penicillin G, 20 million units daily for 14–28 d	Given in divided doses every 4 h
Asymptomatic tick bite	
No treatment or single dose of 200 mg doxycycline	For pregnant women, a 10-d course of amoxicillin may be considered
Asymptomatic seroconversion	No treatment necessary

are common following treatment and generally resolve over a 6-month period. Patients with disseminated disease are most likely to experience persistent symptoms. These symptoms may be due to retained antigen rather than due to ongoing infection with *B. burgdorferi*, since longer courses of antibiotics have not been shown to shorten their duration. Prolonged courses of antibiotics should be reserved for those patients with evidence of persistent infection with *B. burgdorferi*.

Lyme carditis

Cardiac involvement occurs in up to 10% of untreated patients. Transient and varying degrees of atrioventricular block several weeks to months after a tick bite are the most common manifestations. Other features are pericarditis, myocarditis, ventricular tachycardia, and on rare occasions, a dilated cardiomyopathy; valvular disease is not seen. Carditis is typically mild and self limited although patients may present quite dramatically

in complete heart block, and some require the insertion of a temporary pacemaker. In most cases, carditis resolves completely, even without treatment with antibiotics. Studies examining endomyocardial biopsy specimens from patients with Lyme carditis have indicated that direct invasion of *B. burgdorferi* into myocardium and an associated inflammatory reaction are responsible for the clinical events. Although optimal treatment of carditis is unknown, oral therapy for mild forms of cardiac involvement is usually sufficient. Intravenous antibiotics and cardiac monitoring are recommended for patients with varying, high-degree heart block and more serious cardiac involvement. The benefit of concomitant use of aspirin or prednisone and antibiotics in treating patients with Lyme carditis is uncertain. Despite the generally benign course of Lyme carditis, several cases of permanent heart block have been reported, presumably caused by a vigorous inflammatory response. Short courses of prednisone may be considered in patients with prolonged dense heart block despite adequate antibiotic therapy.

Dilated cardiomyopathy is a rare complication of Lyme disease reported in Europe but not yet in the United States. The majority of the patients were from endemic areas for Lyme disease, had other clinical features of disease, and were seropositive for anti-*B. burgdorferi* antibodies. Their myopathy was cured by antibiotic treatment.

Early neurologic disease

Early neurologic involvement occurs in 15% to 20% of untreated patients and appears within 2 to 8 weeks after the onset of disease. Manifestations include cranial nerve palsies, meningitis or meningoencephalitis, and peripheral neuritis or radiculoneuritis, often appearing in combination. Unilateral or bilateral seventh nerve palsies are the most common neurologic abnormalities. Presenting symptoms depend upon the area of the nervous system involved: patients with meningitis present with fever, headache, and a stiff neck; those with Bannwarth's syndrome (primarily in Europe) develop severe and migrating radicular pain lasting weeks to several months; and those with encephalitis have concentration deficits, emotional lability, and fatigue. In patients with early CNS involvement analysis of CSF typically reveals a lymphocytic pleocytosis. Specific antibodies against *B. burgdorferi* may also be present and concentrated in the CSF relative to the serum concentration; they are useful to confirm disease.

Intravenous antibiotics are recommended for all cases of neuroborreliosis except isolated seventh nerve palsy. Patients presenting with a Bell's-like palsy who have features that suggest possible CNS involvement, such as high fever, headache, or stiff neck, should undergo a lumbar puncture looking for evidence of more extensive disease. The most experience in the treatment of CNS Lyme disease has been with aqueous penicillin and third-generation cephalosporins. Although optimal duration of therapy is unknown, it is recommended that patients be treated for two to four weeks. Ceftriaxone, in doses of 1 to 2 g/day, is the agent of choice because of better CNS penetration and ease of administration. Patients with persistent symptoms after recommended antibiotic therapy pose a particular management problem. It is often unclear whether these symptoms are due to resolving inflammation or ongoing infection. Meningitis and sensory symptoms usually resolve within days to weeks; other features may take months to improve. In most cases it is not necessary to continue antibiotic therapy until complete recovery.

Late manifestations

ARTHRITIS

Arthritis is the dominant feature of late Lyme disease, occurring in up to 60% of untreated patients days to years after initial infection (mean of 6 months). The initial pattern of involvement may be migratory arthralgias (early) followed in 60% of patients by intermittent attacks of arthritis lasting from days to months. Large joints, particularly the knee, are most commonly involved. Swelling is often prominent, with large effusions and Baker's cysts. Serologic testing in patients presenting with arthritis is positive in almost all cases.

Lyme arthritis has been treated successfully with oral and intravenous antibiotics. In early studies examining response to intravenous benzathine penicillin, 2.4 million units intramuscularly weekly for 3 weeks, 7 of 20 patients responded compared with 0 out of 20 in the control group. Intravenous ceftriaxone 2 to 4 g daily for 2 to 4 weeks has been thought to be superior to benzathine penicillin. Oral regimens using doxycycline, 100 mg twice a day for 4 weeks, and amoxicillin plus probenecid, 500 mg of each orally four times a day for 4 weeks, have reported success in 18 of 20 patients and 16 of 18 patients, respectively. Response to antibiotics is typically excellent but effusions may take months to

resolve completely. An additional 4 weeks of oral antibiotic therapy has been recommended for patients with persistent arthritis following initial 4-week treatment.

A small subgroup of Lyme arthritis patients develop a chronic, potentially erosive arthritis unresponsive to antibiotics. These patients often have major histocompatability class II gene products, HLA DR4, accompanied by strong serum IgG responses to *Borrelia* outer surface proteins A or B (OspA or OspB). Repeated courses of antibiotics have not been shown to improve clinical outcome. Treatment with anti-inflammatory medications and intra-articular steroid injections can be helpful in reducing joint swelling. Surgical synovectomy has cured a number of such patients. Resolution of the arthritis eventually occurs; in some patients it may take up to 3 to 5 years.

LATE NEUROLOGIC LYME DISEASE

Chronic neurologic syndromes, which are relatively uncommon, may occur months to years after initial infection. Cognitive dysfunction, affective changes, seizures, ataxia, peripheral neuropathies, and chronic fatigue have all been reported. The most common late-stage neurologic syndrome reported in the United States, called Lyme encephalopathy, is characterized by subtle cognitive impairment. Because these complaints are often nonspecific and may be associated with post-Lyme syndromes, it is important to look for and document evidence of ongoing *B. burgdorferi* infection. Lymphocytic pleocytosis is uncommon in late neurologic disease, but increased intrathecal *B. burgdorferi*-specific antibodies may well be present. Careful evaluation with neuropsychological testing can help to distinguish cognitive abnormalities in Lyme disease from those associated with chronic fatigue states and depression. Chronic neurologic dysfunction usually improves with antibiotics but may not completely reverse. Late neurologic manifestations of Lyme disease are treated with intravenous antibiotics. Agents with demonstrated efficacy are aqueous penicillin and third-generation cephalosporins. Doxycyline, both oral and intravenous forms, have been reported to be successful in treating late CNS Lyme disease in Europe.

OCULAR DISEASE

Ocular lesions in Lyme disease are rare, but have involved every portion of the eye and vary depending on the stage of the disease. The most common ophthalmic presentations in early disease include conjunctivitis, photophobia, and neuro-ophthalmologic manifestations due to cranial nerve palsies. The incidence of seventh nerve palsies is similar in Europe and the United States. The most severe ocular manifestations occur in late stages; they include episcleritis, symblepharon, keratitis, iritis, choroiditis, panuveitis, and retinal vasculitis. Serologic testing in these patients is typically positive.

Experience treating late ocular lesions in Lyme disease is scanty. The most success has been with the use of intravenous ceftriaxone in doses of 2 to 4 g daily for 10 to 14 days.

PREGNANCY

Intrauterine transmission of *B. burgdorferi* is uncommon, usually occurring in cases of obvious disseminated infection during pregnancy. No uniform pattern of congenital anomaly has been reported. Prenatal exposure to Lyme disease has not been found to be associated with an increased risk of adverse pregnancy outcome. Optimal treatment of the pregnant patient with Lyme disease is unknown, but the recommended regimens have not been associated with adverse outcomes. Oral antibiotics for early localized disease is sufficient, and intravenous antibiotics are recommended for patients with symptoms suggesting disseminated disease.

TICK BITES

The risk of infection from a deer tick bite in a Lyme disease endemic area is low. In mice, infected ticks have been attached for over a 36-hour period before significant risk of developing Lyme disease occurred. In a controlled double-blind study in patients with tick bites, no patient asymptomatically seroconverted, no treated patient developed EM, and the 2 of 182 untreated patients who did develop EM were successfully treated with oral antibiotics. These results support marking and watching a tick bite, and should EM develop, treating it early, when antibiotics are most effective. A single dose of doxycycline has been shown to be effective in reducing the development of Lyme disease. The Infectious Diseases Society of America (IDSA) guidelines recommend offering the single-dose doxycycline if the attached tick can be reliably identified as an adult or nymphal *I. scapularis* tick, it is estimated to have been attached for >36 hours, prophylaxis can be started within 72 hours after tick detachment, and the local rate of infection of these ticks

with *B. burgdorferi* is greater than 20%. Doxycycline prophylaxis for children under 8 years is not recommended.

SEROPOSITIVE PATIENT WITH NONSPECIFIC SYMPTOMS

Patients with nonspecific symptoms such as myalgias, arthralgias, concentration difficulties, and fatigue are frequently tested for Lyme disease. Some patients, especially those from endemic areas, test positively and are treated for presumed Lyme disease, often without improvement in their symptoms. In several studies over 50% of patients reporting to Lyme disease clinics did not have evidence of Lyme disease, and the reason for a lack of response to antibiotics was an incorrect diagnosis. Objective clinical evidence in support of the diagnosis of Lyme disease should be sought prior to initiating antibiotics, treatment should be given for the recommended duration and then discontinued, and the patient observed for resolution of symptoms.

POST-LYME DISEASE SYNDROME

Some patients continue to have subjective symptoms after completion of recommended courses of antibiotics for Lyme disease. Symptoms typically include arthalgias, myalgias, fatigue, and neurocognitive difficulties. A study of patients treated for EM reported that approximately 5% to 15% of patients experienced subjective symptoms when evaluated 6 to 12 months after treatment. Such symptoms may persist for 5 or more years after treatment. This postinfectious syndrome does not appear to be related to persistent infection with *B. burgdorferi*. In a study of patients with post-Lyme disease syndrome there were no significant outcome differences between the groups who received either intravenous ceftriaxone for 30 days followed by oral doxycycline for 60 days and those that received placebo. The IDSA guidelines do not recommend antibiotic therapy for patients with chronic (>6 months) subjective symptoms after recommended treatment regimens for Lyme disease.

PREVENTION OF LYME DISEASE

Recommended personal protective measures against tick bites include wearing light-colored clothing, long-sleeve shirts, and long pants; tucking pant legs into socks; using a tick repellent on clothing and exposed skin; and performing regular body checks for ticks, strategies that require significant self-motivation. Environmental strategies include the application of acaricides onto vegetation where the ticks live, acaricides delivered directly to tick hosts to kill ticks on the animals, and excluding deer from areas. The last is not practical in most environments.

Public interest in human and veterinary vaccines prompted researchers to develop a safe and effective vaccine for the prevention of Lyme disease. The results of two large safety and efficacy trials using recombinant OspA preparations reported the vaccine to be safe and effective in preventing Lyme disease in most people. LYMErix^{tm} was approved by the US Food and Drug Administration (FDA) for use in individuals aged 15 and older in 1999. The vaccine manufacturer discontinued production in 2002, citing insufficient consumer demand. Protection provided by this vaccine diminishes over time. Individuals that received the Lyme disease vaccine prior to 2002 are probably no longer protected against Lyme disease.

SUMMARY

Antibiotic regimens are recommended according to results of clinical trials and evolving clinical judgments, and depend upon the stage of infection and the organ system involved. Successful eradication of the infecting organism, *B. burgdorferi*, appears to occur in the majority of patients with Lyme disease using these treatment guidelines. Patients with persistent symptoms following antibiotic therapy, particularly those with previous evidence of disseminated disease, pose a difficult management problem. Most persistent symptoms are likely due to retained antigens and not the result of persistent infection or to noninfectious sequelae such as fibromyalgia. In the former patients, resolution of symptoms occurs over the course of weeks to months and does not require prolonged courses of antibiotics; in the latter, treatment is that of the associated syndrome. Rarely, persistent or recurrent symptoms are due to continued or recurrent infection and require additional courses of antibiotics. Such patients require careful diagnostic evaluation to determine the need for additional treatment.

165. Relapsing fever borreliosis

Sally J. Cutler

HISTORY

The relapsing fever spirochetes comprise a number of different species (Table 165.1) with many transmitted by specific tick species. *Borrelia recurrentis* is the notable exception in that it is transmitted by clothing lice.

CLINICAL PRESENTATION

The chief sign is that of fever, often accompanied by chills, headaches, arthralgia, myalgia, and tachycardia. Other signs may include jaundice, petecheal rash, conjunctivitis, nausea, hepatosplenomegaly, and epistaxis. Infection with *Borrelia*

Table 165.1 Characteristics of relapsing fever borrelliae

Organism name	Arthropod vector/reservoir	Vertebrate reservoirs	Clinical infection	Geographic region
B. recurrentis	*Pediculus humanus humanus*	Man	LBRF – human	Africa (formerly worldwide)
B. baltazardii	Unknown	Unknown	TBRF – human	Iran
B. crocidurae	*Ornithodoros sonrai*	Rodents	TBRF – human	West Africa
B. duttonii	*Ornithodoros moubata*	Man	TBRF – human	Africa (Central, Eastern)
B. hermsii	*Ornithodoros hermsi*	Rodents	TBRF – human; canine	Canada, Western USA
B. hispanica	*Ornithodoros marocanus; Ornithodoros occidentalis; Ornithodoros kairouanensis* (formerly *Ornithodoros erraticus*[a])	Rodents	TBRF – human	Algeria, Morocco, Portugal, Spain, Tunisia
B. latyschewii	*Ornithodoros tartakovskyi*	Rodents; reptiles	TBRF – human	Central Asia, Iran, Iraq
B. mazzottii	*Ornithodoros talaje*	Armadillos; rodents	TBRF – human	Southern USA, Mexico, Guatemala
B. merionesi	*Ornithodoros costalis* *Ornithodoros merionesi*	Rodents	Unknown	North Africa
B. microti	*Ornithodoros erraticus*[b]			Africa, Iran
B. parkeri	*Ornithodoros parkeri*	Rodents	TBRF – human	Western USA
B. persica	*Ornithodoros tholozani*	Rodents; bats	TBRF – human; cat	Asia, Middle East
B. turicatae	*Ornithodoros turicata*	Rodents	TBRF – human; canine; birds	USA, Mexico
B. venezuelensis	*Ornithodoros rudis*	Rodents	TBRF – human	Central and South America

[a] *Ornithodoros erraticus* represented a complex. Recent taxonomic molecular studies redressed the phylogeny suggesting that *O. erraticus sensu stricto* is not an efficient vector for *Borrelia*.

[b] Molecular confirmation of *O. erraticus* identity unavailable at time of writing.

Abbreviations: LBRF = louse-borne relapsing fever; TBRF = tick-borne relapsing fever.

Table 165.2 Treatment of relapsing fever borreliosis

Antibiotic	Dosage used	Duration	Comments
Penicillin	400 000–600 000 IU daily	7 to 14 d	Single dose can be curative for LBRF CNS involvement
Tetracycline	200–250 mg BID to 500 mg QID	7 to 14 d	Single dose can be curative for LBRF
Doxycycline	200-250 mg 4 mg/kg/d	7 to 14 d	Can be used as prophylaxis (200 mg d 1, then 100 mg daily 4 d post exposure)
Erythromycin	500 mg QID (50 mg/kg children)	7 to 14 d	During pregnancy or children
Chloramphenicol	500 mg QID (12.5 mg/kg children)	7 to 14 d	During pregnancy or children
Ceftriaxone	2 g daily	7 to 14 d	CNS involvement

Abbreviation: CNS = central nervous system.

duttonii has been associated with significant perinatal mortality in endemic regions such as Tanzania.

Although eventually eliminated by the adaptive immune response, repeat infections can occur in a previously infected individual.

TREATMENT (TABLE 165.2)

Cases are usually managed with penicillin, doxycycline, or tetracycline treatment. Some prefer penicillin as it is believed that this makes Jarisch–Herxheimer reactions (JHR) less likely. Less frequently, cephalosporins, erythromycin, and chloramphenicol have been used.

JHR

The JHR was first described by Adolf Jarisch in 1895 and later by Karl Herxheimer in 1902, in relation to another spirochetal infection, syphilis, but this also occurs in approximately 5% of relapsing fever patients upon treatment. Patients may show an exacerbation of symptoms or "therapeutic shock" during the initial 24 hours post commencing treatment. The JHR is mediated by a release of pyrogenic cytokines (including tumor necrosis factor-α [TNF-α], interleukin [IL]-6, and IL-8) and is treated symptomatically.

TRANSMISSION AND PATHOGENESIS

Transmission of tick-borne relapsing fever (TBRF) occurs during the feeding of *Ornithodoros* soft ticks (up to 20–30 minutes), generally whilst their host is sleeping. The spirochetes may be present within the tick salivary glands, coxal fluid, and feces, facilitating transmission to their vertebrate host. Transovarial transmission occurs for some TBRF borreliae.

Unlike TBRF, in louse-borne relapsing fever (LBRF) the borreliae within the louse vector penetrate the louse's gut epithelium where they can multiply in the louse hemolymph and are also able to be excreted in louse feces, but do not undergo transovarial transmission. Human transmission occurs through crushing lice or their feces into skin abrasions often through scratching.

Once the human is infected, spirochetes multiply in the blood, sometimes to levels of up to $100\,000/mm^3$. This spirochetemia evokes the typical febrile response after which this infection is named. The induced antibody response clears the bloodborne infection; however, the spirochetes soon re-emerge having undergone antigenic variation. A new wave of infection follows that again is eventually controlled through the host's antibody response. Clinically, up to 4 to 5 febrile episodes can occur in LBRF, whilst up to 13 relapses have been recorded for TBRF. Persistence within the human host is a result of a complex interplay of antigenic variation, complement evasion strategies, erythrocyte rosetting, and potentially other mechanisms.

The spirochetes show varying neurotropic potential. This can promote cerebral hemorrhage, for example with *B. recurrentis*. They cross the placenta with associated fetal loss through abortion or congenital infection, particularly *B. duttonii*. Myocarditis and hepatic failure may complicate infection with some of the more virulent members of the relapsing fever borreliae (*B. recurrentis/B. duttonii*), where mortality can reach 10% in untreated cases.

LABORATORY DIAGNOSIS

Microscopy has been the primary diagnostic approach, with demonstration of the spirochetes in blood with Wright's or Giemsa stains, silver staining, or the use of dark-field microscopy for observing motile spirochetes (Figure 165.1). Whilst these methods can detect the causative species, sensitivity is poor, particularly for some species such as *Borrelia crocidurae* where the blood burden is lower than for example *B. recurrentis*. This is further complicated by the need to collect blood during febrile episodes. It is not possible to differentiate species using microscopy.

Animal inoculation can recover and identify cultivable strains. Cultivation can also be achieved from clinical samples into specialized media (such as BSKII) but this is technically demanding. This has been largely superseded by molecular identification approaches, and molecular diagnostics are currently the mainstay for both detection and typing of relapsing fever borreliae.

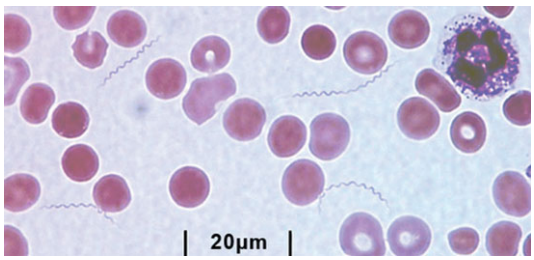

Figure 165.1. Motile spirochetes.

CURRENT EPIDEMIOLOGY

The relapsing fever spirochetes have been divided into those in the Old World and New; however, with improving phylogenetic tools, this division now appears artificial. The prevalence of tick-borne strains correlates with specific regions, particularly African TBRF, probably resulting from climatic conditions conducive for its tick vector. This has not been the case for louse-borne *B. recurrentis*, which was formerly worldwide, but now is restricted to areas where clothing lice persist.

Figure 165.2 depicts the global location of relapsing fever.

It is increasingly apparent that the burden of relapsing fever infections in endemic regions is underdiagnosed. Recent reports from Senegal have suggested that this is the cause of some 13% of fevers presenting at local dispensaries, representing an alarming 11 to 25 cases per 100 person-years. Studies of febrile patients in Morocco have suggested that 20.5% were TBRF cases. Although not at these levels, cases are more frequently being detected in the USA.

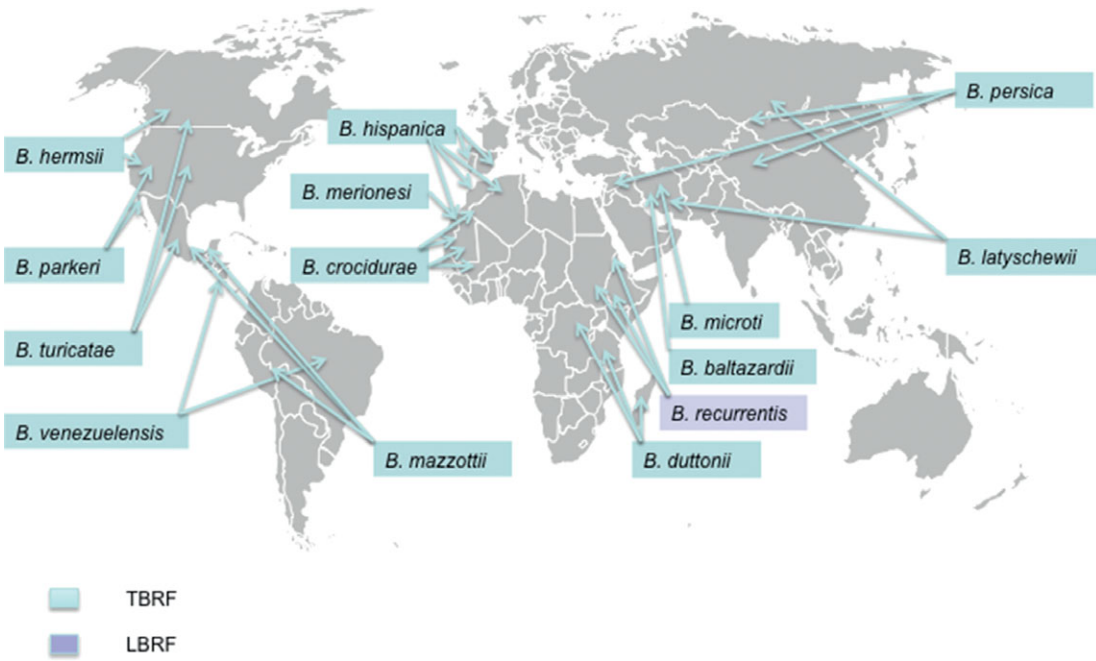

Figure 165.2. Global location of relapsing fever.

Epidemiology of LBRF has changed drastically with the reduced level of infestation with clothing lice. The infection remains in areas of extreme poverty such as Ethiopia, sometimes spilling into adjacent regions, such as an outbreak in the Darfur region of Sudan. During this outbreak between 1999 and 2000 some 20 000 cases occurred with a 10% mortality rate.

RESERVOIRS OF INFECTION

The majority of relapsing fever spirochetes are zoonoses with vertebrate reservoir species (Table 165.1). In the majority of cases, these reservoir species are rodents; however, bats, birds, and reptiles may also have a reservoir role. The notable exceptions are *B. recurrentis* and *B. duttonii*, both of which have an exclusive human reservoir. Many also consider the tick vector a reservoir of infection for TBRF, facilitated by the impressive longevity of these ticks that can survive for many years with their infecting spirochetes.

RISK GROUPS

Both LBRF and TBRF have their greatest burden among those living in extreme poverty.

Occupational contact with tick-infested environments has resulted in clusters of infection, particularly among military personnel who have used caves during training activities, with a resulting clinical burden of up to 6.4 cases/100 000 in Israel. Similarly, conservation workers are at risk. Imported cases have been encountered through migration and tourism, typically in rural regions where intermittently used holiday accommodation has provided refuge for reservoir hosts and their associated tick vectors.

CONTROL AND PREVENTION

Relapsing fever spirochetes remain susceptible to penicillin, tetracycline/doxycycline, chloramphenicol, ceftriaxone, and erythromycin (Table 165.2). Wide use of antimicrobials coupled with improvements in living conditions has reduced the incidence of infection. This is not so apparent for the tick-borne forms of disease that persist in their longer-lived tick vector/reservoirs and through zoonotic vertebrate reservoir species. The burden of TBRF among subsistence agro-pastoralist communities in developing nations remains substantial. Use of acaricides has met with some success, but costs are prohibitive. If contact is unavoidable, doxycycline prophylaxis has been used for short-term prevention.

166. Leptospirosis

Christopher D. Huston

Leptospirosis is an infection with spirochetes from the genus *Leptospira*. Infections are most commonly caused by *Leptospira interrogans*, of which more than 200 serovars infect humans. People become infected by exposure to animal urine or urine-contaminated surface water. *Leptospira* penetrate intact mucous membranes and abraded skin and disseminate widely via the bloodstream. Symptoms develop 7 to 12 days after exposure. Most patients have an abrupt onset of a self-limited, 4- to 7-day anicteric illness characterized by fever, headache, myalgias, chills, cough, chest pain, neck stiffness, and/or prostration (Table 166.1). An estimated 10% of patients will present with jaundice, hemorrhage, renal failure, and/or neurologic dysfunction (Weil's disease). The major clinical manifestations of disease result from infection of capillary endothelial cells leading to vasculitis (Table 166.2).

Classically, leptospirosis has been considered a biphasic illness. However, many patients with mild disease will not have symptoms of the secondary "immune" phase of illness, and patients with very severe disease will have a relentless progression from onset of illness to jaundice, renal failure, hemorrhage, hypotension, and coma. The illness is biphasic in about half of patients, with relapse occuring approximately 1 week after resolution of the initial febrile illness. A late complication is anterior uveitis, seen in up to 10% of patients months to years after convalescence. Leptospirosis in pregnancy is associated with spontaneous abortion, but it is not known to increase the rate of congenital anomalies.

Case-fatality rates for leptospirosis are less than 1%, and the illness is usually self-limited. Liver and renal dysfunction are reversible, with return to normal function over 1 to 2 months. The mortality rate for icteric disease has been reported in different studies to be 2.4% to 11.3%, with deaths resulting from renal failure, gastrointestinal and pulmonary hemorrhage, and the adult respiratory distress syndrome.

Table 166.1 Symptoms and signs of leptospirosis

Abrupt onset (70%–100%)
Fever, chills, rigors (98%)
Headache (93%–97%)
Myalgias, muscle tenderness (40%–80%)
Vomiting, diarrhea, abdominal pain (30%–95%)
Conjunctival suffusion (33%–100%)
Hepatomegaly (5%–22%; 80% of icteric cases)
Splenomegaly (5%–25%)
Meningeal signs (12%–44%)
Mental status changes (7%–21%)
Oliguria (10%)
Cough (10%–20%)
Chest pain (11%)
Skin rash (9%–18%)
Jaundice (1.5%–6%)

DIAGNOSIS

Leptospirosis most often manifests as a nonspecific flu-like illness, so recognition of epidemiologic risk factors is essential (Table 166.3). Occupational exposure to animal urine (e.g., veterinarians) has classically been considered the chief epidemiologic risk, but recent outbreaks highlight the importance of recreational water use (e.g.,

Table 166.2 Pathogenesis of leptospirosis

Table 166.3 Epidemiology of leptospirosis

Leptospira are excreted in animal urine and survive in the environment for up to 6 mo
Disease is common in the tropics, especially in urban slums
Incubation period ranges from days up to 4 wk after exposure (mean 10–12 d)
Recreational exposures include windsurfing, kayaking, swimming, and adventure tourism
Occupational exposures: New Zealand dairy farmers (incidence of 1.1 infections/10 person-years), Glasgow sewer workers (3.7/10 person-years), and US Army soldiers undergoing jungle warfare training in Panama (4.1/10 person-years) Veterinarians, abattoir workers, and others with exposure to rat urine/bites (homeless people, rodent control workers)
Outbreaks seen after floods

Table 166.4 Laboratory findings of leptospirosis

Renal failure – acute interstitial nephritis (15%–70%)
Jaundice with only 2- to 3-fold elevations in transaminases and alkaline phosphatases, conjugated bilirubinemia (2%–60%)
Myositis with elevated creatine phosphokinase (MM band) (20%–62%)
Thrombocytopenia (50%)
Cerebrospinal fluid pleiocytosis (80%–90%): $\leq$300 cells/mm^3, lymphocyte predominance
Abnormal chest radiographs (20%–70%) Patchy alveolar pattern in lower lobes with or without interstitial/alveolar hemorrhage
Electrocardiogram abnormalities: sinus tachycardia, myocarditis, first-degree atrioventricular block
ELISA for IgM antibodies most sensitive test in first week of illness, but limited specificity
Microagglutination test (MAT) for leptospirosis antibodies positive within first 1–2 wk of illness

reservoirs) and risks associated with travel, especially to Southeast Asia or for adventure tourism. Epidemiologic risks should be sought in patients with a flu-like illness, respiratory illness, aseptic meningitis, acute hepatitis, acute renal failure, pericarditis, atrioventricular block, or anterior uveitis. In some developing countries, leptospirosis is more common than hepatitis A as a cause of acute hepatitis. The prominent myalgias, conjunctival suffusion, elevated serum creatine phosphokinase, and the relatively mild (2- to 3-fold) elevations in transaminases seen in leptospirosis may help to distinguish icteric leptospirosis from acute viral hepatitis (Table 166.4). Although prolonged incubation ($\geq$1 week) may be required, it is sometimes possible to grow the organism from blood or cerebrospinal fluid collected during the first 7 to 10 days of illness. Urine cultures may also be intermittently positive for up to 3 months. However, the diagnosis is usually made retrospectively by a 4-fold rise in IgG antibody titer as measured by the microscopic agglutination test (MAT). Serovar-specific agglutinins appear within the first 1 to 2 weeks of illness and peak at 3 to 4 weeks. The sensitivities of culture and the MAT are low, and, although not species or serovar specific, enzyme-linked immunosorbent assay (ELISA) kits to detect immunoglobulin M (IgM) antibodies enable diagnosis during the first week of illness.

Table 166.5 Treatment of leptospirosis

Outpatient treatment: doxycycline, 100 mg PO BID for 7 d in adults
Severe infection requiring hospitalization: penicillin, 6 million U IV qd or ceftriaxone, 1 g IV/IM qd
Chemoprophylaxis: 200 mg doxycycline PO 1$\times$/wk
Jarisch–Herxheimer reaction rare

THERAPY

Antibiotic treatment is most beneficial when started within 4 days of illness. Doxycycline, 100 mg orally twice daily for 7 days started within 48 hours of illness, decreased the duration of illness by 2 days in one study, and is recommended for mild illness. Penicillin at a dosage of 6 million units per day has been successful for early treatment of severe disease, and ceftriaxone (1 g daily) appears to be equally efficacious and has the benefits of simpler dosing schedules and potential intramuscular administration (Table 166.5). A benefit of antibiotic therapy given later in the disease course has not been uniformly seen. Jarisch–Herxheimer reactions (fever, rigors, hypotension, and tachycardia) rarely occur on initiation of antibiotic therapy. Supportive care and treatment of the hypotension, renal failure (including dialysis), and hemorrhage that can complicate leptospirosis are crucial for a good outcome.

167. *Mycoplasma*

Ken B. Waites

Mycoplasmas are the smallest free-living organisms and are unique among prokaryotes in that they lack a cell wall, a feature that is largely responsible for their biologic properties and lack of susceptibility to many commonly prescribed antimicrobial agents. Mycoplasmas are usually mucosally associated, residing primarily in the respiratory and urogenital tracts and rarely penetrating the submucosa, except in the case of immunosuppression or instrumentation, when they may invade the bloodstream and disseminate to many different organs and tissues throughout the body. Intracellular localization occurs in some species and may contribute to chronicity that characterizes many mycoplasmal infections.

There are at least 17 species of mycoplasmas and ureaplasmas for which humans are believed to be the primary host, and numerous others of animal origin that have been detected occasionally, most often in the setting of immunosuppression. Several human mycoplasmal species are commensals in the upper respiratory or lower urogenital tracts. Five species are responsible for the majority of clinically significant infections which may come to the attention of the practicing physician. These species are *Mycoplasma pneumoniae*, *Mycoplasma hominis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, and *Ureaplasma parvum*. *Mycoplasma fermentans* is another mycoplasma of human origin that may behave as an opportunist. *M. fermentans* has been detected in throat cultures of children with pneumonia, in some cases when no other etiologic agent was identified, but the frequency of its occurrence in healthy children is not known. This mycoplasma has also been detected in adults with an acute influenza-like illness and in bronchoalveolar lavage specimens from patients with the acquired immunodeficiency syndrome and pneumonia. *Mycoplasma amphoriforme* is the newest human mycoplasma to be described. It has been detected in a small number of patients with recurrent bronchitis, but its true role as a human pathogen has not yet been established. Other mycoplasmas of animal origin occasionally cause zoonotic infections.

MYCOPLASMA PNEUMONIAE RESPIRATORY DISEASE

M. pneumoniae occurs endemically and occasionally epidemically in persons of all age groups, most commonly in school-age children, adolescents, and young adults. The common misconception that *M. pneumoniae* disease is rare among very young children and older adults has sometimes led to failure of physicians to consider this organism in differential diagnoses of respiratory infections in these age groups. Failure to consider *M. pneumoniae* as an etiologic agent in cases of severe pneumonia may also lead to misdiagnosis since this organism can cause severe respiratory disease that has caused death in a few cases. *M. pneumoniae* is perhaps best known as the primary cause of "walking or atypical pneumonia," but the most frequent clinical syndrome is tracheobronchitis or bronchiolitis, often accompanied by upper respiratory tract manifestations. Typical complaints can persist for weeks to months and include hoarseness, fever, cough which is initially nonproductive but later may yield small to moderate amounts of non-bloody sputum, sore throat, headache, chills, coryza, and general malaise. The throat may be inflamed but cervical adenopathy is uncommon. Bronchopneumonia, involving one or more lobes, often develops in infected persons, accounting for 20% or more of community-acquired pneumonias overall, and an even greater percentage in closed populations such as college dormitories, military barracks, and prisons. The incubation period is generally 1 to 3 weeks and spread throughout households often occurs. Epidemiologic studies have shown *M. pneumoniae* was second only to *Streptococcus pneumoniae* as an etiologic agent of pneumonia in adults requiring hospitalization.

Hospital admission may be necessary in about 10% of children and adults, but recovery is usually complete without sequelae. Some people may experience extrapulmonary complications at variable time periods after onset of or even in the absence of respiratory illness. Such complications most commonly include skin rashes, pericarditis, hemolytic anemia, arthritis, meningoencephalitis, peripheral neuropathy, and pericarditis. Other nonspecific manifestations include nausea, vomiting, and diarrhea. Mycoplasmal infection may also be associated with exacerbations of asthma. Whether the organism can act independently in the pathogenesis of asthma has not been firmly established, but the fact that it can induce a number of inflammatory mediators such as IgE and that administration of macrolide antibiotics improves lung function of asthmatic persons with evidence of mycoplasmas in their airways suggests this possibility is worthy of further study. Some cases of fulminant mycoplasmal infection resulting in death, usually in otherwise healthy persons, have been described. It seems likely that serious disease occurs more often than is currently appreciated, but goes undetected when specific tests to detect *M. pneumoniae* are not performed. A major advance in the understanding of the mechanisms behind the clinical manifestations of *M. pneumoniae* disease is the discovery of an exotoxin similar to pertussis toxin that induces ciliostasis and airway vacuolization, elicits a lymphocytic and eosinophilic airway exudate, and upregulates various cytokines and chemokines.

Autoimmune reaction is thought to be responsible for many of the extrapulmonary complications associated with mycoplasmal infection. However, *M. pneumoniae* has been isolated from extrapulmonary sites such as synovial fluid, cerebrospinal fluid (CSF), pericardial fluid, and skin lesions and it has also been detected by polymerase chain reaction (PCR) assays in various extrapulmonary sites. Therefore, direct invasion must always be considered. The frequency of direct invasion of these sites is unknown because the organism is rarely sought.

The hemogram is often normal, but about one-fourth of patients may develop leukocytosis and one-third may demonstrate an elevated erythrocyte sedimentation rate. The cellular response of the sputum is mononuclear, with no bacteria visible by Gram stain. In about 50% of patients, a cold agglutinin titer of $\geq$1:32 may develop by the second week of illness, disappearing by 6 to 8 weeks. This is not a specific test for *M. pneumoniae*, since other microorganisms may induce

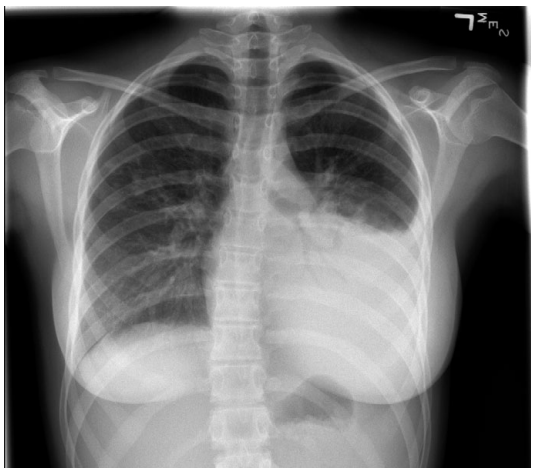

Figure 167.1 Chest radiograph of a female adolescent with PCR-proven mycoplasmal pneumonia, demonstrating bilateral infiltrates. (Radiograph courtesy of T. Prescott Atkinson, MD.)

similar reactions. Several viruses, *Chlamydia pneumoniae*, *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Legionella* species, and even some mycobacteria or fungi can produce infections which are clinically indistinguishable, and which may occur simultaneously with mycoplasmal infection.

Lung involvement tends to be unilateral, but can be bilateral. Diffuse reticulonodular or interstitial infiltrates involving the lower lobes appearing as streaks radiating from the hilus to the base of the lung are the most common radiographic abnormalities. True lobar consolidation is uncommon, but pleural effusion may develop in about 25% of cases. Abnormalities on chest radiographs often appear more severe than the clinical condition of the patient would predict. A typical radiographic presentation of mycoplasmal pneumonia is shown in Figure 167.1.

Due to widespread lack of diagnostic services, length of time until results can be obtained, impracticality of obtaining diagnostic specimens, and similarity of clinical syndromes due to different microorganisms, clinicians often do not attempt to obtain a microbiologic diagnosis in mild to moderately ill outpatients suspected of having *M. pneumoniae* infection and elect to treat empirically. However, if the illness is of sufficient severity to require hospitalization, search for a specific microbiologic etiology is justified. If mycoplasmal respiratory infection is to be confirmed, culture, molecular-based, and/or serologic tests are necessary. Clinical laboratories may offer culture service through a reference laboratory familiar with the

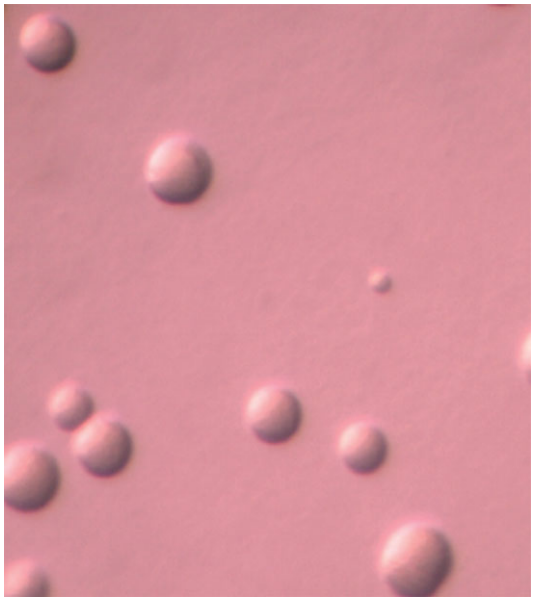

Figure 167.2 Spherical colonies of *Mycoplasma pneumoniae* approximately 100 μm in diameter growing on SP4 agar. Magnification: 126×.

complex cultivation requirements of mycoplasmas. Respiratory tract specimens suitable for culture include throat swabs, sputum, tracheal aspirates, bronchial lavage fluid, pleural fluid, or lung biopsy tissue according to the patient's clinical condition. Care should be taken in specimen collection, inoculation into a suitable transport medium, such as SP4 broth, at bedside whenever possible, and not allowing desiccation. Freezing at −70°C is advised if specimens cannot be transported to the diagnostic laboratory immediately after collection. Growth in culture is slow, requiring ≥3 weeks in some cases. Growth of a glucose-fermenting mycoplasma in SP4 broth and development of microscopic spherical colonies approximately 100 μm in diameter on SP4 agar as shown in Figure 167.2 are presumptive evidence of *M. pneumoniae*. Since some of the upper respiratory commensal mycoplasmal species may also grow on this medium, it is advisable to confirm the identity of the organisms using the PCR assay. Due to the turnaround time, expense, and limited availability, culture is rarely used for routine diagnosis of *M. pneumoniae* infection.

Serology has been used historically to confirm *M. pneumoniae* infection. Enzyme-linked immunosorbent assays are preferred over complement fixation assays or cold agglutinin titers. Since primary infection does not guarantee protective immunity against future infections and residual antibody may remain from earlier encounters with the organism, there has been a great impetus to develop sensitive and specific tests that can differentiate between acute or remote infection. Definitive diagnosis requires seroconversion documented by paired serum specimens obtained 2 to 4 weeks apart and assayed at the same time. Although single-titer qualitative and quantitative IgM or IgA assays purported to detect current infection have now become available, IgM can sometimes persist for many weeks after acute infection and as many as 50% of adults may not mount a detectable IgM response. Conversely, some children may not mount a measurable IgG response. Therefore, reliance on a single serologic test can be clinically misleading and paired assays for both IgM and IgG are recommended. Even then, the interpretation of serologic results can sometimes be complex and inconclusive.

Molecular-based systems for rapid detection of *M. pneumoniae* alone or in combination with other respiratory pathogens are now available through reference laboratories. Some of these assays are commercially sold and others have been developed by individual laboratories for their own use. Given the limitations of culture and serology, molecular-based detection, when available, is the method of choice for detection of acute *M. pneumoniae* infection.

TREATMENT OF *MYCOPLASMA PNEUMONIAE* INFECTIONS

Formerly it was believed that mycoplasmal respiratory infections were entirely self-limited and no antimicrobial treatment was indicated. More recently it has been shown that appropriate antimicrobial therapy will shorten the symptomatic period and hasten radiologic resolution of pneumonia and recovery, even though organisms may be shed for several weeks. In general, the clinical efficacy of antimicrobial therapy is correlated with severity of pneumonia and elapsed time of illness before treatment is begun. A summary of treatment alternatives for *M. pneumoniae* respiratory infections is provided in Table 167. 1.

M. pneumoniae is generally susceptible to macrolides, ketolides, tetracyclines, and fluoroquinolones such that in vitro susceptibility testing to guide therapy is not indicated at present. Susceptibility testing would also be impractical most of the time because clinical isolates are generally not available. Macrolide resistance in *M. pneumoniae* has been known to occur for many years, but

Table 167.1. Treatment options for respiratory tract infections caused by *Mycoplasma pneumoniae*[a]

Drug	Route	Dosage/24 h		Comments
		PEDIATRIC	ADULT	
Doxycycline	PO	4 mg/kg loading dose d 1, then 2–4 mg/kg/d in 1–2 doses × 10–14 d	200 mg loading dose d 1, then 100 mg q12h × 9–13 d	Pregnancy category D Tetracyclines are contraindicated in children under 8 years of age unless there is no other alternative
	IV	Same as PO	Same as PO	
Tetracycline	PO	25–50 mg/kg/d in 4 doses × 10–14 d	250–500 mg q6h × 10–14 d	Pregnancy category D Tetracyclines are contraindicated in children under 8 years of age unless there is no other alternative
	IV	10–20 mg/kg/d in 2–4 doses × 10–14 d	500 mg–1 g q6–12h × 10–14 d	
Erythromycin	PO	20–50 mg/kg/d in 3–4 doses × 10–14 d	250–500 mg base/stearate q6h or 400–800 mg ethylsuccinate q6h × 10–14 d	Pregnancy category B
	IV	25–40 mg/kg/d in 4 doses × 10–14 d	Same as PO	
Azithromycin	PO	10 mg/kg/d on d 1, then 5 mg/kg/d × 4 d; not to exceed 250 mg/d	500 mg d 1, then 250 mg qd × 4 d or 2 g given as a single dose	Pregnancy category B IV formulation is not approved for use in persons under 16 years of age
	IV	Not recommended	500 mg qd IV × 2 d, then 500 mg PO qd × 7–10 d	
Clarithromycin	PO	15 mg/kg/d in 2 doses × 7–14 d	250–500 mg q12h × 7–14 d (immediate release) or 1 g qd × 7 d (extended release)	Pregnancy category C No IV formulation is available
Levofloxacin	PO	Not recommended	750 mg qd × 5 d	Pregnancy category C Fluoroquinolones are not approved for use in persons under 18 years of age
	IV	Not recommended	Same as PO	
Moxifloxacin	PO	Not recommended	400 mg qd × 7–14 d	Pregnancy category C Fluoroquinolones are not approved for use in persons under 18 years of age
	IV	Not recommended	Same as PO	
Gemifloxacin	PO	Not recommended	320 mg qd × 7 d	Pregnancy category C Fluoroquinolones are not approved for use in persons under 18 years of age. No IV formulation is available

[a] Treatment recommendations are primarily for management of community-acquired pneumonia with antibiotics approved for treatment of this condition, although they are also appropriate for tracheobronchitis due to this organism. Choice of routes for administration is dependent on the severity of the clinical condition being treated. Most *M. pneumoniae* infections can be adequately treated with oral medication.

it was believed to be quite rare and of minimal clinical significance. Over the past decade, the emergence of macrolide-resistant *M. pneumoniae* infections in Asia that have resulted in diminished clinical response to macrolide therapy is worrisome. This resistance now affects the majority of *M. pneumoniae* isolates in China and Japan. Limited data suggest that such resistant organisms also occur in the United States and various countries in Europe, but are still relatively uncommon. Recent data suggest 10% macrolide resistance in the USA. Oral erythromycin has long been a drug of choice for mycoplasmal respiratory infections, but its use has been reduced due to the availability of better-tolerated drugs in this class with improved pharmacokinetics and shorter treatment durations.

The macrolides clarithromycin, azithromycin, and dirithromycin are broad-spectrum agents used primarily for treatment of community-acquired respiratory infections caused by a wide array of bacteria. These agents are very active in vitro against *M. pneumoniae* and inhibit its growth at comparable or lower minimum inhibitory concentrations (MICs) than those of erythromycin, unless the strain has ribosomal mutations conferring macrolide resistance. All of these drugs have proven clinical efficacy and approved therapeutic indications for pneumonia caused by this organism. Care must be taken because of numerous

potential drug interactions with these macrolides. Clarithromycin and azithromycin are available as pediatric oral suspensions and azithromycin is also available as an intravenous formulation in addition to the oral formulations. Tetracycline and its analogs are also effective in vivo and in vitro, but should not be used in children due to potential bone and tooth toxicity. Clindamycin is effective in vitro, but limited reports suggest it may not be active in vivo and should not be considered a first-line treatment. None of the β-lactams, sulfonamides, or trimethoprim is effective in vitro or in vivo against *M. pneumoniae*.

Fluoroquinolones exhibit bactericidal antimycoplasmal activity, but are less potent in vitro than the macrolides against *M. pneumoniae*. Development of quinolones with documented clinical efficacy and approved indications for treating *M. pneumoniae* has been driven largely by the need for therapeutic alternatives for β-lactam- and macrolide-resistant *S. pneumoniae*, and the desire for agents that can be used as empiric monotherapy for respiratory infections due to other typical and atypical organisms. At the present time, quinolones are not approved for use in persons under 18 years of age, but these drugs are rapidly achieving widespread use for treatment of respiratory infections in adults, mainly in the ambulatory setting, and represent reasonable alternative therapies for *M. pneumoniae* disease, particularly in the setting of macrolide resistance.

Mycoplasmas are slow-growing organisms; thus one would logically expect respiratory infections to respond better to longer treatment courses than might be offered for other types of infections. Thus, a 14- to 21-day course of oral therapy is appropriate for some drugs, but some of the newer agents have shown clinical efficacy against mycoplasmal pneumonias with shorter durations. For example, a 5-day course of oral azithromycin is approved for treatment of community-acquired pneumonia due to *M. pneumoniae*.

In addition to the administration of antimicrobials for management of *M. pneumoniae* infections, other measures such as cough suppressants, antipyretics, and analgesics should be given as needed to relieve the headaches and other systemic symptoms. Since most extrapulmonary manifestations are diagnosed late in the course of disease, the benefit of early treatment is unknown. However, limited information suggests that high-dose steroid therapy and/or intravenous immunoglobulin therapy may help reverse neurologic symptoms, if present. If treatment of extrapulmonary mycoplasmal infections is necessary, and/or the patient is immunosuppressed, selection of an agent that exhibits bactericidal activity such as a fluoroquinolone may be most appropriate and administration of the drugs for longer durations may be required.

Fortunately, the treatments of choice for *M. pneumoniae* are appropriate for many of the other microbial agents responsible for community-acquired respiratory infections. This is especially important in view of the fact that in the major proportion of ambulatory patients seeking medical care, the identity of their infectious organism is never determined.

GENITAL *MYCOPLASMA* AND *UREAPLASMA* INFECTIONS

Ureaplasma spp. and *M. hominis* can be isolated from the lower genital tract in the majority of sexually active women; their occurrence is somewhat less frequent in men. The presence of genital mycoplasmas in so many asymptomatic persons has made it difficult to prove their pathogenic potential. For some conditions such as cystitis, male urethritis, and urinary calculi for *Ureaplasma* spp. and pelvic inflammatory disease (PID) for *M. hominis*, evidence is sufficient to implicate these organisms as etiologic agents in a portion of clinical cases. For other conditions such as prostatitis and bacterial vaginosis the evidence is not as clear-cut. Only a subgroup of otherwise healthy adult men and women who are colonized will develop clinically significant genitourinary disease due to these organisms, but the risk factors are poorly understood. Table 167.2 summarizes diseases believed to be associated with or caused by genital mycoplasmas and ureaplasmas.

The ability of genital mycoplasmas to be transmitted vertically from mother to offspring in utero or at the time of delivery has led to considerable efforts to ascertain their role as perinatal pathogens. Isolation of *Ureaplasma* spp. from the chorioamnion of pregnant women has been consistently associated with histologic chorioamnionitis and is inversely related to birth weight, even when adjusting for duration of labor, rupture of fetal membranes, and presence of other bacteria. *Ureaplasma* spp. can be isolated from endometrial tissue of healthy, nonpregnant women, indicating that they may be present at the time of implantation and might therefore be involved in early pregnancy losses. Numerous studies have shown that the presence of ureaplasmas alone or with other bacteria in the chorioamnion is independently

Table 167.2. Diseases associated with or caused by genital mycoplasmas

Disease	*Ureaplasma* spp.	*M. hominis*	*M. genitalium*

Extragenital disease in adults[a]	+	+	−

− = no association or causal role demonstrated. In some conditions for *M. genitalium* this may reflect the fact that no studies using appropriate techniques to detect this organism have been performed.

+ = causal role.

± = significant association and/or strong suggestive evidence, but causal role not proven.

[a] These include conditions such as septic arthritis, bloodstream invasion, abscesses, wound infections, lung infections, endocarditis, and osteomyelitis.

associated with birth at <37 weeks of gestation regardless of the duration of labor. The ability of ureaplasmas to invade the amniotic fluid early in gestation and initiate inflammation provides the setting through which they can also produce inflammation in the lower respiratory tract of the developing fetus and neonate. Over the past several years there has been increasing evidence that these organisms may cause congenital pneumonia and initiate events leading to chronic lung disease of prematurity or bronchopulmonary dysplasia.

Superficial mucosal colonization in the newborn period tends to be transient and without sequelae, but neonates, especially those born preterm, have been shown to be susceptible to development of a variety of systemic conditions due to either *M. hominis* or ureaplasmas, including bacteremia and meningitis.

For many years *U. urealyticum* was the only species known to infect humans. However, this organism was eventually subdivided into two separate species, *U. urealyticum* and *U. parvum*, based on 16S rRNA sequences. *U. parvum* is the more common species isolated from clinical specimens, but both species may occur simultaneously. Most clinical studies have not distinguished between the two species except in very recent years because sophisticated nucleic acid amplification tests are necessary to discriminate between them. Evidence is accumulating that suggests *U. urealyticum* may be more pathogenic in some conditions such as male urethritis.

Extragenital infection with *M. hominis* and/or *Ureaplasma* spp. beyond the neonatal period is usually associated with some degree of immunocompromise, such as congenital hypogammaglobulinemia, iatrogenic immunosuppression following solid organ transplantation, or with invasive procedures such as instrumentation of the urinary tract. Ureaplasmas and other mycoplasmas are the most common etiologic agents of septic arthritis in the setting of congenital antibody deficiencies and should be considered early when attempting to diagnose these conditions.

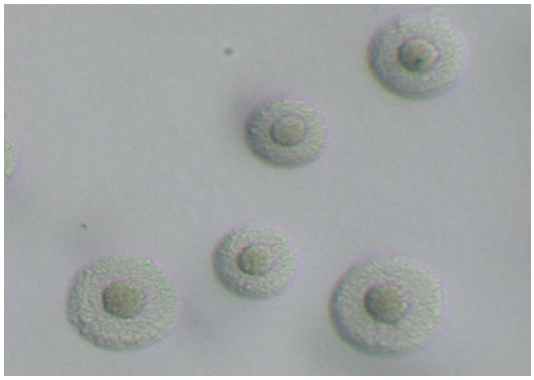

Figure 167.3 Fried egg-type colonies of *Mycoplasma hominis* up to 110 μm in diameter. Magnification: 132×.

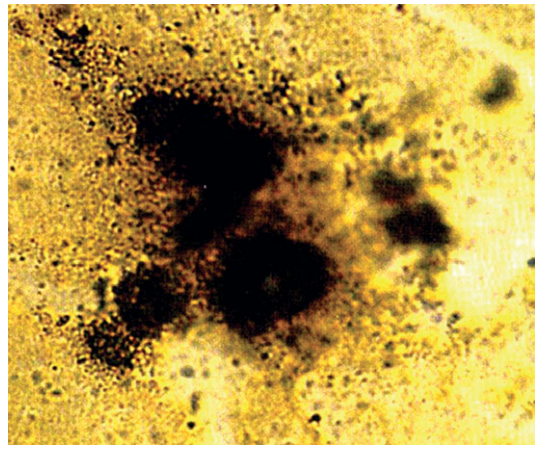

Figure 167.4 Granular brown urease-positive colonies of *Ureaplasma* species 15 to 60 μm in diameter from a vaginal specimen growing on A8 agar. Magnification: 100×.

M. genitalium was first isolated from urethral specimens in men with urethritis. This mycoplasma occurs much less commonly in the lower urogenital tract of asymptomatic persons than *M. hominis* or *Ureaplasma* spp. Availability of the PCR assay has greatly enhanced understanding of the role of *M. genitalium* in human disease. Several clinical studies support a causal role in male urethritis, indicating it may be responsible for 15% to 25% of all cases, as well as female cervicitis, and PID.

Both *M. hominis* and ureaplasmas grow more rapidly and can therefore be detected in cultures of appropriate specimens within 2 to 5 days. Proper handling and bedside inoculation of transport broth enhance recovery of these organisms. Urethral or wound swabs, cervicovaginal or prostatic secretions, urine, respiratory specimens such as those described for *M. pneumoniae*, CSF, and blood or other body fluids or tissues are appropriate for culture, depending on the clinical setting. Cultures are available mainly through larger hospital laboratories or reference laboratories. *M. hominis* produces typical fried-egg colonies on agar and can be presumptively identified by rate of growth, colony morphology (Figure 167.3), and arginine hydrolysis. Definitive identification requires characterization by PCR. Ureaplasmas can be identified to genus level by typical colony morphology on A8 agar and urease activity (Figure 167.4). At present there are no commercial serologic assays or rapid detection tests available for routine diagnostic studies for any of the genital mycoplasmas in the USA, but several PCR-based assays are sold in various European countries. Techniques for isolation of *M. genitalium* in culture have been described, but its extremely slow growth, sometimes requiring several weeks to form colonies, and difficult cultivation have essentially limited diagnostic measures to PCR assays. PCR tests to detect *M. genitalium* for clinical diagnostic purposes are available through reference laboratories, though such testing is still uncommonly performed at the present time.

Genitourinary or extragenital diseases from mycoplasmas warrant appropriate diagnostic tests when available and treatment if infection is confirmed. This is of particular importance if the organisms are recovered in the absence of other possible microbial etiologies and if the infection is present in a normally sterile site. Practitioners will usually have to rely upon familiarity with clinical syndromes typically due to genital mycoplasmas and treat empirically if facilities for laboratory diagnosis are not readily available. Many of the conditions associated with a mycoplasmal etiology can also be due to a variety of microbial agents and some conditions such as PID can be polymicrobial. Therefore, the selection of drugs must take into account multiple causes.

TREATMENT OF GENITAL *MYCOPLASMA* AND *UREAPLASMA* INFECTIONS

Oral tetracyclines have historically been the drugs of choice for use against urogenital infections due to *M. hominis*, but resistance now occurs in 20% to 50% of isolates. A survey of clinical isolates of *Ureaplasma* spp. from various states found that 45% possessed the *tetM* transposon conferring resistance to this class of drugs. The degree of resistance may vary according to geographic area, type of patient population, and

Table 167.3 Treatment options for urogenital and systemic infections in adults caused by *Mycoplasma hominis*, *Mycoplasma genitalium*, and *Ureaplasma* species[a]

Drug	Route	Dosage/24 h	Comments
Doxycycline	PO IV	200 mg loading dose d 1, then 100 mg q12h × 7 d Same as PO	Pregnancy category D. Tetracyclines are contraindicated in children <8 yr of age unless no other alternative is available. Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*. Treatment failures have been described for *M. genitalium* urethritis
Tetracycline	PO IV	250–500 mg q6h × 7 d 125–500 mg q6–12h × 7 d	Pregnancy category D. Tetracyclines are contraindicated in children <8 yr of age unless no other alternative is available. Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*
Erythromycin	PO IV	250–500 mg q6h × 7 d Same as PO	Pregnancy category B. Not active against M. *hominis*
Azithromycin	PO IV	500 mg × 1 d then 250 mg × 4 d or 1 g as a single dose 500 mg/d × 2 d, then 500 mg PO qd	Pregnancy category B. Not active against *M. hominis*. In vitro resistance and treatment failures have been described for *M. genitalium* urethritis
Clindamycin	PO IV	150–450 mg q6h × 7 d 150 – 900 mg q6–8h × 7 d	Pregnancy category C. Not active against *Ureaplasma* spp.
Ofloxacin	PO IV	200 – 400 mg q12h × 7 d Same as PO	Pregnancy category C. Fluoroquinolones are not approved for use in persons under 18 yr of age
Levofloxacin	PO IV	500 mg qd × 7–14 d Same as PO	Pregnancy category C. Fluoroquinolones are not approved for use in persons under 18 yr of age
Moxifloxacin	PO IV	400 mg q12h × 10 d Same as PO	Pregnancy category C. Fluoroquinolones are not approved for use in persons under 18 yr of age. Moxifloxacin does not have approved indications for treatment of urogenital infections, but it has been effective in men with *M. genitalium* urethritis who failed treatment with azithromycin

[a] Treatment options are based on accepted regimens for urogenital infections involving other microorganisms that are expected to be suitable for infections caused by genital mycoplasmas based on in vitro susceptibility data in circumstances where there are no approved microbiologic indications. Route and duration of treatment are dependent on the severity of the clinical condition being treated. For extragenital and/or systemic infections, particularly those involving immunocompromised persons, a longer duration of treatment may be necessary than those listed. Joint infections may require several weeks to months of antimicrobial administration. Recommendations are based primarily on published case reports due to the lack of objective data from clinical trials.

previous exposure to antimicrobial agents. Recent reports of fluoroquinolone resistance in both *M. hominis* and *Ureaplasma* spp. in the United States and Europe lend support to the recommendation that in vitro susceptibility testing is indicated when these organisms are recovered from a normally sterile body site, from immunocompromised hosts, and/or from persons who have not responded to an initial treatment. Susceptibility testing can be accomplished in 3 to 5 days by a reference laboratory once the organism is isolated. Treatment alternatives for urogenital infections in adults and neonatal infections are provided in Tables 167.3 and 167.4, respectively.

Clindamycin is an alternative treatment for *M. hominis* and is effective against tetracycline-resistant strains, but it is much less active against *Ureaplasma* spp. In contrast, macrolides are generally active against ureaplasmas, but *M. hominis* is typically resistant to macrolides. Occasional macrolide-resistant ureaplasmas have been reported. A single dose of azithromycin is approved for treatment of urethritis due to *Chlamydia trachomatis*, and has been shown to work as well clinically as doxycycline in persons with urethritis due to *Ureaplasma* spp. Despite in vitro susceptibility, tetracycline or erythromycin treatment of vaginal mycoplasmas is not always successful.

Clinical studies have encountered treatment failures with the tetracyclines for urethritis caused by *M. genitalium* and it was initially believed azithromycin would be a better option. However, reports of treatment failures with azithromycin and detection of *M. genitalium* isolates with elevated MICs to this drug indicate it may not always be effective. Macrolide-resistant *M. genitalium* infections have been successfully treated with fluoroquinolones (e.g., moxifloxacin), but resistance has also been documented.

Table 167.4. Treatment options for neonatal infections with *Mycoplasma hominis* and *Ureaplasma* species[a]

Drug	Route	Dosage/24 h	Comments
Doxycycline	PO IV	4 mg/kg loading dose d 1, then 2–4 mg/kg/d in 1–2 doses × 10–14 d Same as PO	Tetracyclines are contraindicated in children <8 yr of age unless no other alternative is available. Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*. This drug has been used to successfully treat neonatal meningitis due to *M. hominis* and *Ureaplasma* spp., but treatment failure has been reported with *Ureaplasma* spp.
Tetracycline	PO IV	25–50 mg/kg/d in 4 doses 10–20 mg/kg/d in 2–4 doses	Tetracyclines are contraindicated in children <8 yr of age unless no other alternative is available. Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp possessing *tetM*
Chloramphenicol	PO IV	Not recommended For neonates up to 2 wk of age, use 25 mg/kg/d in 1 dose, thereafter 50 mg/kg/d in 1 dose	Chloramphenicol has been used successfully to treat neonatal meningitis due to *M. hominis* and *Ureaplasma* spp., but there has also been a report of treatment failure with *M. hominis*. Frequent monitoring of hematologic parameters and blood levels of the antibiotic are necessary due to its potential toxicity.
Erythromycin	PO IV IV	20–50 mg/kg/d in 3–4 doses 25–40 mg/kg/d in 4 doses Same as PO	Not active against *M. hominis*. Despite poor CSF penetration, this drug has been used successfully to treat neonatal meningitis due to *Ureaplasma* spp., but treatment failure has also been reported
Clindamycin	PO IV	10–25 mg/kg/d in 3–4 doses × 10–14 d 10–40 mg/kg/d in 3–4 doses. Do not exceed 15–20 mg/kg/d	Not active against *Ureaplasma* spp. This drug has been used to successfully treat neonatal infections due to *M. hominis*

[a] No treatment guidelines for neonatal infections with genital mycoplasmas are available. Treatment options have been compiled based on in vitro susceptibility data and information described in published case reports. No dosages have been established or approved for neonates, so amounts listed are based on data applicable to older infants and children.

Despite occasional reports of resistance, fluoroquinolones have become useful alternatives for treatment of certain infections caused by *M. hominis*, *M. genitalium*, and *Ureaplasma* spp. within the urogenital tract and in some extragenital locations. Activity of fluoroquinolones is not affected by tetracycline or macrolide resistance. Ciprofloxacin and ofloxacin are generally less active in vitro against these organisms than levofloxacin and moxifloxacin. Very few clinical antibiotic trials have included microbiologic data specific for genital mycoplasmas and there have been no systematic comparative evaluations of treatment regimens for extragenital infections in adults or for neonatal infections. Thus, treatment recommendations in Tables 167.3 and 167.4, including dosages and duration, are based largely on in vitro susceptibility data, outcomes of treatment trials evaluating clinical response to syndromes such as PID and urethritis that may be due to genital mycoplasmas, and individual case reports. For infections such as urethritis that may be venereally transmitted, sexual contacts of the index case should also receive treatment.

Experience with mycoplasmal or ureaplasmal infections in immunocompromised patients, especially those with hypogammaglobulinemia who have been the best studied, demonstrate that even though mycoplasmas are primarily noninvasive mucosal pathogens in the normal host, they have the capacity to produce destructive and progressive disease. Infections may be caused by resistant organisms refractory to antimicrobial therapy and require prolonged administration of a combination of intravenous antimicrobials, intravenous immunoglobulin, and/or antisera prepared specifically against the infecting species for weeks to months. Even with aggressive therapy, relapses are still likely to occur. Repeat cultures of affected sites may be necessary to monitor in vivo response to treatment.

Isolation of *M. hominis* or *Ureaplasma* spp. from CSF in neonates with pleocytosis, progressive hydrocephalus, or other neurologic abnormality; pericardial fluid; pleural fluid; tracheal aspirate in association with respiratory disease; abscess material; or blood are justification for specific treatment in critically ill neonates when no other verifiable microbiologic etiologies of the clinical condition are apparent. Parenteral tetracyclines have been used to treat neonatal meningitis due to either *M. hominis* or *Ureaplasma* spp., despite contraindications, but erythromycin or other macrolides such as azithromycin for *Ureaplasma* spp., clindamycin for *M. hominis*, or chloramphenicol for either species are alternatives. No single drug has been successful in every

instance in eradication of these organisms from CSF of neonates. Even though azithromycin has a number of advantages over erythromycin from the pharmacokinetic standpoint, there has been minimal clinical experience with this drug in treatment of neonatal ureaplasmal infections and there are no guidelines for its use in this setting. Overall treatment guidelines for neonates are the same as for urogenital and systemic mycoplasmal infections in adults with appropriate dosage modifications based on weight, except that the intravenous route should be used for serious systemic infections. Duration of treatment and drug dosages for neonatal mycoplasmal infections have not been critically evaluated, but a minimum of 10 to 14 days of therapy is suggested based on experience in individual cases where microbiologic follow-up has been assessed.

Other mycoplasmal species

A variety of mycoplasmal species can be isolated from the upper respiratory tract or urogenital tracts of humans. Some of them occur fairly commonly as commensals in healthy persons, whereas others are found less often. Some of these organisms have been implicated in case reports as agents of invasive disease, usually in immunosuppressed persons. No guidelines for their detection or treatment are possible due to the infrequency of isolation and lack of clinical isolates on which in vitro susceptibility tests have been performed. In the case of *M. fermentans*, its antimicrobial susceptibilities are generally similar to those of *M. hominis*, but scant information is available for other species. If a clinical isolate of one of these opportunistic mycoplasmal species is available, in vitro susceptibility tests can sometimes be performed to guide treatment, providing the organism will grow well enough in vitro to perform the test. Otherwise, empiric use of drugs shown to be effective against other mycoplasmal species as shown in Tables 167.1, 167.3, and 167.4 should be considered, with the choice being based on the type of infection encountered and status of the host.

168. *Chlamydia pneumoniae*

Margaret R. Hammerschlag

The first isolates of *Chlamydia pneumoniae* were obtained serendipitously during trachoma studies in the 1960s. After the recovery of a similar isolate from the respiratory tract of a college student with pneumonia in Seattle, Grayston and colleagues applied the designation TWAR after their first two isolates, TW-183 and AR-39. *C. pneumoniae* appears to be a common human respiratory pathogen. The mode of transmission remains uncertain but probably involves infected respiratory tract secretions. Spread of *C. pneumoniae* within families and enclosed populations, such as military recruits, prisons, and nursing homes, has been reported. The proportion of community-acquired pneumonia in children and adults associated with *C. pneumoniae* infection has ranged from 0% to >44%, varying with geographic location, the age group examined, and the diagnostic methods used. Early studies that relied on serology suggested that infection in children younger than 5 years was rare; however, subsequent studies using culture and/or polymerase chain reaction (PCR) have found the prevalence of infection in children beyond early infancy to be similar to that found in adults.

Studies that have used culture have found a poor correlation with serology, especially in children. Although 7% to 13% of children 6 months to 16 years of age enrolled in two multicenter pneumonia treatment studies were culture positive and 7% to 18% met the serologic criteria for acute infection with the microimmunofluorescence (MIF) test, they were not the same patients. Only 1% to 3% of the culture-positive children met the serologic criteria, and approximately 70% were seronegative. By age 20, approximately 50% of persons will have detectable anti-*C. pneumoniae* immunoglobulin G (IgG). Seroprevalence may exceed 80% in some populations.

Prolonged culture positivity lasting from several weeks to several years after acute infection has been reported. Asymptomatic nasopharyngeal carriage also occurs in 2% to 5% of adults and children. The role that asymptomatic carriage plays in the epidemiology of *C. pneumoniae* is not known, but possibly these persons serve as a reservoir for spread of infection.

Most *C. pneumoniae* infections are probably mild or asymptomatic. Initial reports emphasized mild atypical pneumonia clinically resembling that associated with *Mycoplasma pneumoniae*. Generally, pneumonia associated with *C. pneumoniae* is not clinically indistinguishable from other pneumonias. Coinfection with other pathogens, especially *M. pneumoniae* and *Streptococcus pneumoniae*, are frequent. *C. pneumoniae* pneumonia has been associated with severe illness and even death, although the role of pre-existing chronic conditions as contributing factors in many of these patients is difficult to assess. In some cases, however, *C. pneumoniae* clearly appears to be implicated as a serious pathogen, even in the absence of underlying disease. *C. pneumoniae* has been isolated from the empyema fluid in several patients with severe pneumonia.

The role of host factors in *C. pneumoniae* infection remains to be determined. *C. pneumoniae* appeared to be responsible for 14% to 19% of episodes of acute chest syndrome in children with sickle cell disease. *C. pneumoniae* infection in these patients appeared to be associated with more severe hypoxia than infection with *M. pneumoniae*. *C. pneumoniae* is also an inflammatory trigger for asthma.

The role of *C. pneumoniae* in upper respiratory infections is less well defined. *C. pneumoniae* has been isolated from the middle ear fluid of children and adults with otitis media and has also been implicated as a cause of pharyngitis. *C. pneumoniae* infection has been implicated in a wide variety of chronic diseases and conditions, including atherosclerosis, Alzheimer's disease, macular degeneration, and arthritis. However, many of these studies are hampered by the lack of standardized methods for the diagnosis of *C. pneumoniae* infection.

LABORATORY DIAGNOSIS

A specific laboratory diagnosis of *C. pneumoniae* infection can be made by identification of the organism from nasopharyngeal or throat swabs, sputa, or pleural fluid, if present, by culture or nucleic acid amplification test (NAAT). The nasopharynx appears to be the optimal site for isolation of the organism. The relative yield from throat swabs and sputum is not known. Isolation of *C. pneumoniae* requires culture in tissue; the organism cannot be propagated in cell-free media. *C. pneumoniae* grows readily in cell lines derived from respiratory tract tissue, specifically, HEp-2 and HL cells. Culture with an initial inoculation and one passage should take 4 to 7 days.

Nasopharyngeal cultures can be obtained with Dacron-tipped, wire-shafted swabs. Each lot of swabs should be treated in a mock infection system to ensure that no inhibitory effects occur on either the viability of cells or recovery of chlamydiae. Specimens for culture should be placed in appropriate transport media, usually a sucrose phosphate buffer with antibiotics and fetal calf serum, and stored immediately at 4°C for no longer than 24 hours. Viability decreases if specimens are held at room temperature. If the specimen cannot be processed within 24 hours, it should be frozen at –70°C until culture can be performed. After 72 hours of incubation, culture confirmation can be performed by staining with either a *C. pneumoniae* spp.-specific or a *Chlamydia* genus-specific (antilipopolysaccharide [anti-LPS]) fluorescein-conjugated monoclonal antibody.

NAATs, specifically real-time PCR, appear to be the most promising technology in the development of a rapid, nonculture method for detection of *C. pneumoniae*. More than 25 in-house PCR assays for detection of *C. pneumoniae* in clinical specimens have been reported in the literature. None of these assays is standardized or extensively validated in comparison to culture for detection of *C. pneumoniae* in respiratory specimens. Recently, a new PCR assay for the detection of *C. pneumoniae* became commercially available, and was US Food and Drug Administration (FDA) cleared in July 2012. The FilmArray assay detects *C. pneumoniae*, *M. pneumoniae*, and *Bordetella pertussis* on the same platform. The system combines nucleic acid extraction, nested PCR, detection, and data analysis in a single-use pouch. However, clinical data on the use of this assay are limited.

Because isolation of *C. pneumoniae* was initially considered to be difficult and limited, emphasis was placed on serologic diagnosis. The microimmunofluorescence (MIF) test is not standardized or FDA approved. Although enzyme immunoassay (EIA) serology test kits offer the promise of standardized performance and objective end points, none have been evaluated adequately in comparison to culture or PCR. Most have been compared only with MIF. None have FDA clearance or approval for use in the United States. One commercial assay, the Medac rELISA, uses a recombinant LPS antigen; others are based on LPS-extracted EBs or synthetic peptides. These kits can measure IgG, immunoglobulin M (IgM), and immunoglobulin A (IgA) antibodies, but cutoffs vary from kit to kit, and the criteria for a positive result (acute infection, past infection) can be very complex. The Centers for Disease Control and Prevention (CDC) has proposed modifications of the serologic criteria for diagnosis of *C. pneumoniae* infection. Although the MIF test was considered to be the only serologic test currently acceptable, the criteria were made significantly more stringent. Acute infection as determined by MIF was defined as a 4-fold rise in IgG or an IgM titer of 16 or greater, and the use of a single elevated IgG titer was discouraged. However, the use of paired sera also affords only a retrospective diagnosis, which is of little help in terms of deciding how to treat a patient. An IgG titer of 16 or greater was considered to indicate past exposure, but neither elevated IgA titer nor any other serologic marker was thought to be a validated indicator of persistent or chronic infection. The CDC did not recommend the use of any EIA for detection of antibody to *C. pneumoniae*.

THERAPY

Chlamydia pneumoniae is susceptible to tetracyclines, macrolides, and quinolones. Most of the treatment studies of pneumonia caused by *C. pneumoniae* published thus far have relied entirely on diagnosis by serology; consequently, microbiologic efficacy could not be assessed. Anecdotal reports have suggested that prolonged courses, up to 3 weeks, of either tetracyclines or erythromycin may be needed to eradicate *C. pneumoniae* from the nasopharynx of adults. The results of two pediatric multicenter pneumonia treatment studies found that 10-day courses of erythromycin and clarithromycin and 5 days of azithromycin suspension were equally efficacious; they eradicated the organism in 79% to 86% of children. Quinolones, including levofloxacin

Table 168.1 Regimens for respiratory tract infection caused by *C. pneumoniae*

Adults	Children
Doxycycline, 100 mg 2 × a day for 14–21 d	Erythromycin suspension, 50 mg/kg/d for 10–14 d
Tetracycline, 250 mg 4 × a day for 14–21 d	Clarithromycin suspension, 15 mg/kg/d for 10 d
Azithromycin, 1.5 g over a period of 5 d	Azithromycin suspension, 10 mg/kg on day 1 followed by 5 mg/kg/d once daily on days 2 to 5
Levofloxacin, 500 mg/d orally or intravenously for 7–14 d	
Moxifloxacin, 400 mg/d orally for 10 d	

and moxifloxacin, also have been demonstrated to have 70% to 80% efficacy in eradicating *C. pneumoniae* from adults with community-acquired pneumonia. Most patients improved clinically despite persistence of the organism. Persistence does not appear to be secondary to the development of antibiotic resistance.

Based on these limited data, regimens for respiratory tract infection caused by *C. pneumoniae* are listed in Table 168.1. Some patients may require retreatment.

169. *Chlamydia psittaci* (psittacosis)

Alfred E. Bacon III

Chlamydia psittaci was identified simultaneously by three investigators in 1930. It is one of four species within the genus *Chlamydia*. Based on RNA sequencing, it is currently considered distinct from *Chlamydia pneumoniae* and *C. trachomatis*, despite phenotypic and physiologic similarities that have taxonomically bound them for many years. The organism is an obligate intracellular pathogen that contains both RNA and DNA but lacks a classic cell wall. These characteristics contribute to both the clinical manifestations and the determination of therapeutic options. *C. psittaci* has a wide range of host species, including birds, humans, and lower mammals. *C. pneumoniae*, however, is found only in humans and *C. trachomatis* only in humans and mice.

The systemic illness associated with *Chlamydia psittaci* has been termed *psittacosis* because of its association with parrots and psittacine birds. Subsequently, many avian species have been found to harbor *C. psittaci* and to transmit the organism to humans, causing disease. The term *ornithosis* would be more appropriate; however, it is not traditional. The organism can be carried for years in birds, remaining latent and causing disease many years after acquisition. Transmission to humans can occur even in the absence of disease in the bird. Excretion in the feces with aerosolization is the typical mode of transmission. Human-to-human transmission has been documented rarely and usually in the setting of severe disease. Healthcare workers have acquired the disease, but it is not felt warranted to isolate patients when hospitalized. Cases of mammal-to-human acquisition have been described in the setting of placental aeration at birth, but these cases are likely caused by the now separate species *Chlamydophila abortus*.

Individuals epidemiologically at risk for *Chlamydia psittaci* infection include abattoir and veterinary workers as well as those exposed to aviaries. Poultry breeders (particularly turkey farmers) are at significant risk, accounting for most outbreaks. A variable degree of illness exists in the birds infected with *C. psittaci*, ranging from asymptomatic to full-blown disease manifested by anorexia, dyspnea, and diarrhea. Birds may resolve the illness spontaneously, and a waxing and waning clinical course is not unusual. Therefore, a history of contact with birds is pertinent even if the bird is seemingly healthy. Up to 20% of patients may not recall bird exposure, but contact as innocuous as mowing a lawn or being exposed to airborne feces is adequate exposure. It remains a distinctly unusual cause of pneumonia with only four cases reported to the Centers for Disease Control and Prevention (CDC) in 2010, compared to an average of 16 cases per year in the preceding decade. New criteria for the diagnosis also contributed to this drop. Underreporting in the setting of accepted clinical criteria may play a role in this lack of recognition.

Vigilance in the workplace and prevention in at-risk bird populations play an increasing role. Quarantine and treatment of imported birds is a mainstay.

CLINICAL SYNDROMES

Following inhalation in aerosol form, the organism travels to the alveoli and then disseminates to regional lymph nodes and the reticuloendothelial system. Dissemination does not always occur, limiting disease to the chest. The organism invades and even multiplies successfully in a wide range of host cells, including macrophages and neutrophils. Multiple organ involvement is not uncommon, and the systemic nature of this disease cannot be overstated.

The classic presentation is one of an atypical pneumonia, although systemic infection in the absence of pneumonia has been well described as a typhoidal disease, even with cutaneous manifestations such as Horder's spots. Cough is often a later clinical sign, preceded by fever, malaise, and often severe headache by a number of

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

days. The presence of severe headache is felt to be a sentinel component of the disease. The incubation period ranges from 5 to 21 days, and in up to 20% of patients no history of exposure to a bird can be elicited. Diarrhea is very common.

Neurologic involvement and encephalopathic features have been reported. Endocarditis, myocarditis, and septicemia can occur. Rash, panniculitis, and even joint disease seen as human leukocyte antigen (HLA)-B27 reactive arthritis occur rarely. Recently, a follicular conjunctivitis has been described caused by "nontrachoma" chlamydia, including *C. psittaci*. Anecdotal reports of vasculitis and cerebral vascular disease have been linked to *C. psittaci* but lack convincing clinical or diagnostic criteria.

Physical findings commonly include pulmonary consolidation and an altered mental status. As with other intracellular pathogens, a temperature–pulse dissociation is often reported. Laboratory data are rarely unique to *C. psittaci* infection; however, hepatocellular damage is present in almost 50% of patients. An abnormal chest x-ray film is evident in 80% of infected individuals, almost uniformly a lobar infiltrate as opposed to a diffuse pattern.

DIAGNOSIS

The diagnosis of *C. psittaci* infection is based on serologic confirmation of exposure to the pathogen in the proper clinical setting. As with most cases of atypical pneumonia, a thorough history looking for exposures, systemic symptoms, and atypical features is crucial. Culturing the organism is difficult and hazardous in the laboratory. Two serologic assays are readily available. A complement fixation antibody assay with a 4-fold or greater change in titer between acute and convalescent phase era confirms the diagnosis. A random titer greater than 1:32 with a compatible illness is presumptively diagnostic. The complement fixation assay, however, does cross-react with *Chlamydia trachomatis* and *C. pneumoniae*. The microimmunofluorescence assay has a higher specificity and can demonstrate immunoglobulin M (IgM) or immunoglobulin G (IgG) antibody directed at *C. psittaci*. Evaluation of acute and convalescent sera is still recommended. However, it is important to note that the serologic response can be blunted when therapy is initiated early.

Rapid diagnostic testing has been utilized rarely in the diagnosis of *C. psittaci* infection: Immunohistochemical identification of *C. psittaci* antigen in clinical specimens has been successfully reported, and real-time polymerase chain reaction applied directly to both culture and clinical specimens has shown great specificity and sensitivity. Unfortunately, these techniques are not readily available in the clinical setting. In the acute setting, when therapy is initiated, the diagnosis of *C. psittaci* infection truly rests on clinical grounds, with an exposure history and a compatible clinical presentation.

THERAPY

The therapy of choice for *C. psittaci* infections, both systemic and limited, is a tetracycline. Doxycycline, 100 mg orally twice a day, is the preferred agent. The systemic nature of the infection and reports of relapsing disease require a prolonged course of therapy. The identification of relapsing disease has led most authors to suggest a course of at least 14 days, and most encourage 21 days total. In the seriously ill population requiring intravenous therapy the dosing is the same for doxycycline. In patients with endocarditis, a more prolonged course is necessary, and patients rarely have survived without valve replacement in addition to prolonged doxycycline therapy.

Traditionally, erythromycin, 500 mg orally four times a day, is the second-line drug for *C. psittaci* pneumonia. Because relapses and failures in therapy have been reported, a 21-day course of therapy is indicated. Newer macrolide agents, particularly azithromycin, have been studied in chlamydial infections, specifically *C. psittaci*. Failure of erythromycin has been reported in pregnancy, and some authors suggest tetracyclines or azithromycin in this setting. Azithromycin appears both in vitro and in vivo to be an excellent alternative to doxycycline. A 7-day course at 10 mg/kg of body weight has been effective in experimental models. This reflects the increased intracellular concentration of this agent as well as the prolonged half-life. Both azithromycin and doxycycline are intravenous options in severe disease. There are fewer data to support the use of clarithromycin, although this agent has been shown to be effective in the treatment of infections caused by other *Chlamydia* species. The new glycocyclic agent, tigecycline, although related to the tetracycline family, should not be considered an adequate therapeutic alternative, with no data to support its use for *C. psittaci*.

In the treatment of conjunctivitis where *C. psittaci* is suspected, a 4- to 10-week course of either

doxycycline or erythromycin is appropriate. More traditional agents have also shown efficacy, including chloramphenicol, 500 mg four times a day for 14 days. Patients failing this regimen have done well with the addition of rifampin.

Many reports in the literature demonstrate a prompt clinical response to doxycycline in patients infected with *C. psittaci*. Therefore, a patient's failure to show symptomatic improvement within 48 hours should prompt a re-evaluation of the diagnosis or a suspicion of deep-seated infection such as endocarditis.

There are growing data on the use of quinolones in the management of *C. psittaci* infections. These agents have shown excellent activity against other *Chlamydia* species. In vitro and animal model data have delineated activity of a broad range of quinolones against *C. psittaci*, most notably ofloxacin, ciprofloxacin, moxifloxacin, and sparfloxacin. Ofloxacin in a dose of 200 mg orally twice daily has shown efficacy in a small population of patients with confirmed infection with *C. psittaci*. The use of levofloxacin at 500 mg daily for 21 days would likely be similarly supported. Failure of quinolone therapy in fulminant disease has been described but more likely reflects a delayed diagnosis and the need for high index of suspicion on presentation.

Johan S. Bakken and J. Stephen Dumler

170. Rickettsial infections

Paul D. Holtom

The Rickettsiaceae are aerobic, small, gram-negative coccobacilli that are obligate intracellular parasites of eukaryotic cells. There are three groups of rickettsiae based on clinical presentation: the spotted fever group, the typhus group, and scrub typhus. *Coxiella burnetii*, the agent that causes Q fever, is covered in this chapter but is now classified in the γ-proteobacteria group, together with *Legionella* and *Francisella tularensis* (Table 170.1).

The pathogenesis of illness due to the rickettsiae is vasculitis. The rickettsiae proliferate in the endothelial lining cells of the small arteries, capillaries, and veins. In Q fever the organisms are inhaled and proliferate in the lungs, causing inflammation and bacteremic seeding of other organs, particularly the liver. All of the important rickettsial infections are vector-borne, whereas Q fever usually results from inhalation of dust contaminated by the birth fluids of domestic ungulates.

In any discussion of the treatment of rickettsioses it is important to stress that proper treatment cannot be given unless the diagnosis is

Table 170.1 Diseases caused by Rickettsia

suspected. Confirmation of the diagnosis is usually serologic and almost always delayed, because antibodies occur no earlier than the second week of illness in any of the rickettsioses. The arthropod-borne rickettsioses are diseases of the spring and summer in temperate climates. Q fever can occur at any season if exposure to aerosols of the organism occurs. Given an appropriate geographic, temporal, and/or occupational history, the triad of fever, headache, and rash should cause the physician to suspect a disease caused by the rickettsiae. As early treatment is important in preventing fatalities, particularly in Rocky Mountain spotted fever (RMSF), therapy should be instituted when the diagnosis is suspected.

ROCKY MOUNTAIN SPOTTED FEVER

RMSF was first described in the late 1800s in the Bitterroot Valley of Montana. Although originally recognized in the western United States, it now has a higher documented prevalence in the South Atlantic states and in the south-central region. The causative agent is *Rickettsia rickettsii*, a member of the spotted fever group of rickettsial infections.

Rickettsia rickettsii is transmitted to humans by the bite of an infected tick. Ticks are both the vectors and the main reservoirs of this agent; the specific tick responsible for transmission varies from region to region: In the eastern United States, the dog tick, *Dermacentor variabilis*, is the usual vector, whereas in the western United States it is the wood tick, *Dermacentor andersoni*. The adult tick transmits the disease to humans during feeding, releasing *R. rickettsii* from the salivary glands after feeding for 6 to 10 hours. Humans can also be infected by exposure to infected tick hemolymph, which may occur during the removal of ticks from persons or domestic animals, especially when the tick is crushed between the fingers. Although the incidence of RMSF has increased from less than two per million in 2000 to over eight cases per million persons in 2008, case-fatality rate has declined to 0.5%.

The incubation of RMSF ranges from 2 to 14 days, with a median of 7 days. Virtually all patients have fever, usually above 38.9°C (102°F). The major diagnostic sign is the rash, seen in approximately 90% of the patients, which usually occurs within 3 to 5 days after the onset of fever. Fewer than half of the patients show the rash during the first 3 days of the illness. The rash typically starts around the wrists and ankles, but it may start on the trunk or be diffuse at onset. Although involvement of the palms is considered characteristic, this does not occur in all patients and often occurs late in the course of the disease (Figure 170.1). Other common symptoms include severe headache, myalgias, and gastrointestinal complaints such as nausea, vomiting, and severe abdominal pain.

Complications of RMSF include meningismus, meningitis, renal failure, pulmonary involvement, hepatic dysfunction with development of jaundice, splenomegaly, myocarditis, and thrombocytopenia. Although in the early reports the case-fatality rate was greater than 20% in the absence of early therapy, in recent series of patients death occurs in 4% to 8% of the cases. In those with fulminant RMSF, death occurs 8 to 15 days after the onset of symptoms.

Diagnosis of RMSF is primarily based on a high clinical suspicion in the setting of a patient with fever, headache, and myalgias with exposure to ticks. Rash is found in only 14% of patients on the first day of illness and in 49% of patients during the first 3 days. A skin biopsy of a rash lesion (when present) can show *R. rickettsii* with immunohistochemistry staining or nucleic acid amplification test. This has a specificity of 100% and a sensitivity of 70% but is useful only in patients who have developed a rash. Serologic diagnosis is retrospective. The use of the polymerase chain reaction is not well established for the diagnosis of RMSF.

Treatment of RMSF requires the administration of an effective antibiotic for 7 days, continuing for 2 days after the patient has become afebrile. Early therapy is important, as the risk of death is five times greater in patients treated

after day 5 of illness. The antibiotic of choice for both adults and children is oral doxycycline, 100 mg every 12 hours for 7 days, or at least 2 days after the patient becomes afebrile. Tetracycline, 25 to 50 mg/kg/day in four doses, is also effective. In patients with hypersensitivity to tetracyclines and in pregnant patients, chloramphenicol, 50 to 75 mg/kg/day, is a less effective alternative. Although fluoroquinolones have shown activity against *R. rickettsii*, they are not recommended because of a lack of clinical experience. Glucocorticosteroids have been given to severely ill patients in the past, but there is no documentation of their efficacy. No vaccine is currently available to prevent RMSF.

OTHER SPOTTED FEVER GROUP RICKETTSIA

Five species of spotted fever group rickettsiae (SFGR) – *R. rickettsii, Rickettsia parkeri, Rickettsia felis, Rickettsia akari*, and *Rickettsia* 364D – are causes of infections in humans in the United States. However, standard serologic assays do not differentiate infections caused by SFGR, and all may be lumped into the diagnostic category of RMSF.

Successful treatment for all of them has been reported using doxycycline (200 mg/day); alternates may be tetracycline (25 mg/kg/day), chloramphenicol (2 g/day), or ciprofloxacin (1500 mg/day) for 5 to 7 days.

Rickettsia akari causes the nonfatal disease rickettsialpox, first reported in 1946 in New York but rarely diagnosed. The usual incidence in New York City is five cases per year, and it has been reported in eastern Europe, South Africa, and Korea. The reservoir for this infection is the house mouse, *Mus musculus*, and the vector for transmission to humans is the mouse mite *Allodermanyssus sanguineus*. A painless papule that ulcerates and forms an eschar occurs at the site of the mite bite some 3 to 7 days before the onset of symptoms in most cases. Manifestations include chills, fever, headache, myalgia, backache, and photophobia. Rigors and profuse diaphoresis may be seen. Within 2 to 3 days after onset, a generalized papulovesicular rash occurs. The rash begins as red papules 2 to 10 mm in diameter that vesiculate and heal by crusting. The disease is usually benign; death and complications are very rare.

EPIDEMIC OR LOUSE-BORNE TYPHUS

This classic plague of humanity is caused by *Rickettsia prowazekii* and transmitted by the human body louse *Pediculus humanus corporis*. The bacteria may remain latent in humans for many years after the initial infection and then relapse when persons are stressed by other disease or deprivations. Thus, during war and refugee exodus, when people are stressed and deprived and poor hygiene promotes the spread of lice, a rickettsemic person may initiate the cycle and cause an epidemic. This relapsing disease is generally milder than an initial attack, presumably because it occurs in a person with some established immunity. This recrudescent typhus is called Brill–Zinsser disease. An extrahuman reservoir has been identified in southern flying squirrels, *Glaucomys volans*, which are found throughout the eastern United States. Humans are infected by flying squirrel fleas.

The characteristic incubation period is 8 to 16 days. The onset is usually abrupt, with intense headache, progressive fever, chills, and severe myalgia. Rash begins on about the fifth day of illness, usually on the axillary folds and upper trunk and spreads centrifugally. The rash begins as pink macules that fade on pressure but progresses to become maculopapular, darker, petechial, and nonfading on pressure. The rash may become confluent and involve the entire body, but the face, palms, and soles are spared. In the pre-antibiotic era, mortality was seen in 13%, occurring a median of 12.5 days after onset of the illness; survivors defervesced a median of 14 days after onset. Indigenously acquired typhus related to flying squirrel exposure is a similar but milder illness.

The established therapy for epidemic typhus is doxycycline (100 mg twice daily), tetracycline (25 to 50 mg/kg/day in four doses), or chloramphenicol (60 to 75 mg/kg/day in four doses) given for 7 to 10 days. In epidemic situations where the availability of doxycycline may be limited, a single dose of 200 mg of doxycycline may be effective, but a small proportion of patients may relapse. No vaccine is currently available for the prevention of typhus; the only prevention available is control of body lice by hygiene and insecticides such as permethrin.

MURINE TYPHUS

Murine typhus, caused by *Rickettsia typhi*, has worldwide distribution, especially in tropical and subtropical seaboard regions. Its most important reservoirs are *Rattus* spp., and the classic vector that spreads the organisms from rats to people is the flea *Xenopsylla cheopis*. Although rats are the primary animal reservoir of *R. typhi*, other

mammals (including opossums and domestic dogs and cats) can also serve as reservoirs.

The disease is clinically less severe than epidemic typhus, with reported case-fatality rates of 1% to 4%. Illness begins 1 to 2 weeks after a bite from an infected flea. At first it is nonspecific, with fever, headache, chills, myalgia, and nausea. Rash is seen in about 20% of patients at presentation and in about 50% sometime during the illness. The skin lesions are macular or maculopapular. The trunk is most often involved, but the extremities are involved in about half the patients who develop rash. The rash may also be seen on the palms and soles. The rash is frequently salmon colored and evanescent, but frank hemorrhagic vasculitic rash may develop. Occasionally, patients develop central nervous system (CNS) abnormalities, hepatic or renal failure, respiratory failure, or hematemesis. Diagnosis is suggested by risk factors and clinical findings, and can be confirmed by a 4-fold or greater rise in antibody titer to *R. typhi* antigens between paired serum specimens taken $\geq$3 weeks apart, or by detection of *R. typhi* DNA in a clinical specimen by polymerase chain reaction (PCR).

Rickettsia typhi infection is treated with doxycycline, tetracycline, or chloramphenicol. Antimicrobial therapy should be continued for 2 to 3 days after defervescence.

SCRUB TYPHUS

Scrub typhus occurs when a larval stage trombiculid mite (chigger), infected with *Orientia tsutsugamushi*, bites a susceptible human host. The disease occurs from Korea and Japan to China, Southeast Asia, India, and south to Australia.

Some 6 to 18 days after a chigger bite, the patient develops high fever, severe headache, mental changes, lymphadenopathy, and myalgia. An eschar may be found at the site of the bite. The severity of the signs and symptoms is widely variable, depending on the virulence of the responsible strain and the degree of susceptibility of the host. After about 5 days a macular rash, sometimes evanescent, may occur, beginning on the trunk and spreading to the extremities. Complications include multiple organ system dysfunction and hemorrhage, pneumonia, heart failure, respiratory failure, and renal failure. Case-fatality rates as high as 30% in untreated patients have been reported, but treatment shortens the duration of illness and essentially eliminates fatalities.

Doxycycline and chloramphenicol are the recommended treatments. Doxycycline can be given as a single dose of 200 mg or for a course of 3 to 7 days. Alternative drugs include rifampin (600–900 mg/day) and azithromycin (500 mg initial dose, then 250 mg daily).

Q FEVER

Q fever, an infection caused by *Coxiella burnetii*, can present as an acute infection with an influenza-like illness, including pulmonary and hepatic involvement, or it can develop into a chronic infection with endocarditis and chronic hepatitis.

Coxiella burnetii is an extremely infectious organism. In fact, a single inhaled organism is sufficient to initiate infection. It is endemic worldwide except in New Zealand. *Coxiella burnetii* infects many species of animals, and the infection usually results in long-lasting parasitism. Q fever in humans is usually caused by the inhalation of aerosolized particles from infected domestic animals; these particles can be airborne over long distances.

C. burnetii is asymptomatic in about half of those infected. Those with clinical illness most commonly have a nonspecific febrile illness, which may be associated with pneumonia, hepatitis, or meningoencephalitis. Patients can go on to develop a chronic illness characterized by endocarditis and granulomatous hepatitis.

The incubation period for Q fever can be as short as 4 to 5 days, but it typically ranges from 9 to 39 days. Fever is the most common symptom, occurring in almost all patients, and the temperature often spikes to 40°C to 40.5°C (104°F to 105°F). Pneumonia is the primary clinical manifestation, with a majority of patients showing abnormalities on their chest radiographs. Other signs and symptoms include chills, headache (often severe and debilitating), retrobulbar pain, myalgias and arthralgias, neck pain and stiffness, pleuritic chest pain, cough, nausea and vomiting, diarrhea, jaundice, hepatomegaly, and splenomegaly. Unlike the rickettsial diseases, Q fever does not usually present with a rash, although a transient erythematous macular rash has been noted in about 4% of patients. The manifestations of Q fever usually resolve within 2 to 4 weeks, although some patients have had fever as long as 9 weeks. Case-fatality rates from acute Q fever are very low (none in most series), but in hospitalized patients the case-fatality rate has been reported as 2.4%. Children usually have a milder acute

disease than adults, but are more likely to have a rash (in up to 50%).

Chronic Q fever is uncommon (<5% of patients with acute infections) and usually manifested by endocarditis. Most patients have preexisting valvular heart disease, often a prosthetic valve. Other manifestations include chronic hepatitis, infections of vascular prostheses and aneurysms, osteomyelitis, and interstitial pulmonary fibrosis. The illness evolves slowly, manifesting any time from a few months to 20 years after the acute infection, and presents clinically as a culture-negative endocarditis, although fever is often absent in Q fever endocarditis. Post-Q fever fatigue syndrome, lasting for several years to life, is the most common chronic manifestation after acute infection, occurring in up to 20% of patients.

The diagnosis of Q fever is based on identifying risk factors and clinical suspicion. Culture is not recommended as it is difficult and dangerous, requiring a biosafety level 3 laboratory. Serologic testing of paired acute and convalescent sera, showing a 4-fold increase of IgG to *C. burnetii* phase II antigen by an indirect immunofluorescence antibody assay, is the most commonly used method for diagnosing acute Q fever. PCR testing of blood or tissue is another diagnostic method, but different tests vary in sensitivity and specificity.

Most acute Q fever infections resolve spontaneously, but because of the concern about the development of chronic Q fever specific antimicrobial therapy should be given. The treatment of choice is doxycycline orally for 2 weeks; some success has been reported with trimethoprim–sulfamethoxazole (TMP–SMX), chloramphenicol, rifampin, and (in vitro) telithromycin.

The treatment of chronic Q fever has never been the subject of controlled studies. No antibiotics have been found to be bactericidal for *C. burnetii*, although several (including tetracycline, doxycycline, TMP–SMX, rifampin, ciprofloxacin, and telithromycin) have been shown to be bacteriostatic. Current recommendations are to give doxycycline together with hydroxychloroquine for at least 18 months. A vaccine for people in at-risk professions is available in Australia, but requires testing before vaccination to identify preexisting immunity, as this can lead to a severe local reaction.

171. Ehrlichiosis and anaplasmosis

Johan S. Bakken and J. Stephen Dumler

Ehrlichiosis is the collective name for infections caused by obligate intracellular gram-negative bacteria in the genera *Ehrlichia*, *Anaplasma*, and *Neoehrlichia*, family Anaplasmataceae. Members of these genera cycle between invertebrate (arthropod) and vertebrate hosts, and some cause human zoonoses. At least seven species cause human tick-borne infection in the United States and Europe, including *Ehrlichia chaffeensis*, the agent of human monocytic ehrlichiosis (HME), *Ehrlichia ewingii*, the agent of human ewingii ehrlichiosis (HEE), *Anaplasma phagocytophilum*, the agent of human granulocytic anaplasmosis (HGA), an *Ehrlichia muris*-like agent (EMLA), the Panola Mountain ehrlichia, an agent phylogenetically similar to *Ehrlichia ruminantium* that has caused fever in humans in the United States, *Ehrlichia canis*, thought limited to canids but identified as an agent of human febrile illness in Venezuela, and *Candidatus* Neoehrlichia mikurensis, which has caused severe sepsis-like conditions in Europe, but mild febrile disease in Asia. While human infection by *Neorickettsia sennetsu* periodically surfaces in Asia, the transmission and disease processes are distinct and it will not be considered here.

Most Anaplasmataceae reside in ixodid (hard-body) ticks, and the bacteria are acquired during the larval stage and passed transstadially with each successive tick stage. *Amblyomma americanum* (the Lone Star tick) is the vector for *E. chaffeensis* and *E. ewingii*, and its range is throughout the south and eastern United States from Maine to Texas. In addition, all documented reports of human infections are limited to North America, although some evidence suggests that they exist in ticks in South America and Asia. In contrast, *A. phagocytophilum* and the *E. muris*-like agent cycle within *Ixodes* species ticks. *Ixodes scapularis* (the black-legged or deer tick) is found in the eastern United States and is a vector for both species. In addition, *Ixodes pacificus* (the western black-legged tick), found in regions of the US Pacific coast (northern California, Oregon, and Washington), and *Ixodes ricinus* and *Ixodes persulcatus*, found in Europe and Asia, respectively, are competent vectors for *A. phagocytophilum*. *Ixodes* species ticks are also vectors for *Borrelia burgdorferi* (the agent of Lyme borreliosis), and most cases of HGA are reported from areas where Lyme borreliosis is endemic.

Thus far, HGA has been reported in 36 US states and in countries in western and central Europe, as well as Russia, China, Korea, and Japan. Active US surveillance in southeastern Missouri identified HME incidence as high as 414 cases per 100 000 population. The incidence for HGA varies from 25 up to 58 cases per 100 000 in endemic regions of Connecticut and Wisconsin. Only a limited number of cases of HEE have been recognized in central US states, but it is anticipated to be common. Clinical cases of infection by the *E. muris*-like agent were recently recognized in up to 48 patients in Wisconsin and Minnesota, and a small fraction of healthy blood donors in Minnesota and Wisconsin have evidence of past exposure. Less than 20 Venezuelan patients with *E. canis* infection, and only a small number of infections by *Candidatus* N. mikurensis, likely transmitted by *I. ricinus* ticks in Europe, have been identified; there is only a single report of Panola Mountain ehrlichia human infection. Most cases of ehrlichiosis present during the period between April and October, and as many as 75% of patients have noted one or more tick bites 1 to 2 weeks prior to the onset of symptoms. Male patients outnumber females by a factor of nearly 3 to 2, and even though HME and HGA affect all age groups, symptomatic infection is less frequent in children. The case-fatality rate is 0.6% and 2.7% for HGA and HME, respectively. Table 171.1 summarizes some of the epidemiologic characteristics associated with HME, HEE, HGA, EMLA-associated illness, and *Candidatus* N. mikurensis infection.

When the tick takes a blood meal, bacteria become injected with the tick saliva into the host. Once injected, the bacteria infect specific circulating leukocytes and cause a nonspecific febrile illness. *Ehrlichia chaffeensis* and EMLA typically infect monocytes and macrophages, whereas *E. ewingii* and *A. phagocytophilum* infect neutrophilic granulocytes; *Candidatus* N. mikurensis has been observed only once in human neutrophils but its definitive target is not yet established. The bacteria adhere to leukocyte membrane receptors to enter cells by endocytosis. There are key differences in the vacuoles with *E. chaffeensis* and *A. phagocytophilum*, underscoring that the agents induce distinct pathogenetic pathways. Regardless, the bacteria reside within cytoplasmic vacuoles, where they interact with the host cell to access nutrients, delivering effector proteins to the host cytosol and nucleus that subvert host cell functions, including intracellular signaling, cell cycle regulation, innate immune responses such as respiratory burst or induction of immune activation, delayed induction of apoptosis, and subversion of autophagy, among others. During this interval, the bacteria multiply in the vacuole to form aggregates called morulae. Eventually, each morula fuses with the cell membrane through exocytosis or the cell is mechanically lysed, liberating bacteria to infect other cells. Most recent investigations of disease pathogenesis focus on the induction of innate, inflammatory, and immune-mediated injury as the major consequence of infection. This suggests that an important target for control of disease could include control of inflammatory and immune responses.

Even though they differ with respect to biology, epidemiology, and ecology, HME, HEE, HGA, and infection with EMLA present as clinically similar illnesses with characteristic, albeit nonspecific alterations in hematology and chemistry laboratory tests. The incubation period for HME, HEE, HGA, and EMLA varies between 1 and 2 weeks following tick exposure or tick bite. The symptoms and signs range from asymptomatic to fatal, and clinical severity increases with patient age and comorbid illnesses. Ehrlichiosis presents as a clinical syndrome most commonly manifest by abrupt onset of fever, shaking chills, severe headache, and myalgia (Table 171.2); a specific diagnosis can be difficult because of the undifferentiated nature of the signs and symptoms. Between one-third and one-half of symptomatic patients require hospitalization for 1 week or longer. Infection with *Candidatus* N. mikurensis can result in either a severe febrile illness that lasts for weeks in the absence of therapy, as observed in Europe where most patients

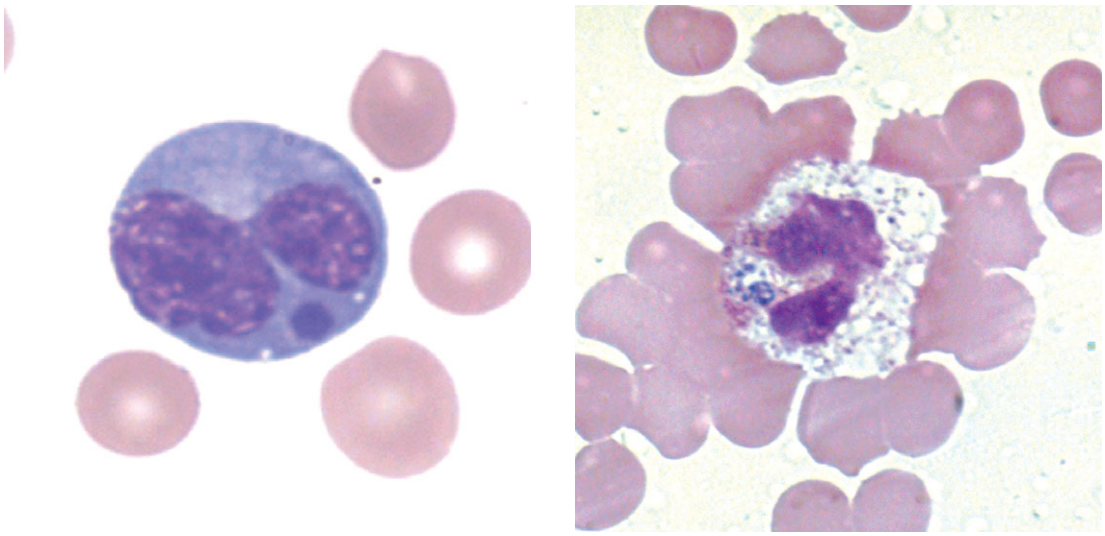

Figure 171.1 *Ehrlichia chaffeensis* morula (**left**) in a peripheral blood monocyte and *Anaplasma phagocytophilum* morula (**right**) in a peripheral blood neutrophil (Wright stain; original magnifications: 360× and 400×, respectively).

had pre-existing immune compromise, or as a mild to moderate and self-limited illness, as observed in Asia where most patients were not immune compromised.

Laboratory abnormalities are nonspecific and include various leukopenia and thrombocytopenia with a differential leukocyte count that reveals increased proportions of band neutrophils and a corresponding decrease in relative and absolute lymphocyte concentrations. In addition, most patients manifest mild to moderate increases in serum transaminase activities reflecting underlying hepatocellular injury. Albeit relatively insensitive, the diagnosis can be confirmed by blood smear examination, because morulae can be observed in peripheral blood leukocytes of 1% to 20% of patients with HME and as many as 60% of patients with HGA during the first week of infection (Figure 171.1). Polymerase chain reaction (PCR) is an excellent tool for diagnosing HME, HEE, HGA, and EMLA during the early stage of infection, and sensitivity >90% and specificity >95% are regularly achieved. However, the availability of these PCR assays is limited to large commercial, academic medical, or public health reference laboratories. More than

95% of patients with HME and HGA form specific antibodies during the course of the infection, and testing of acute and convalescent sera using indirect fluorescent antibody (IFA) tests is currently the most sensitive method for laboratory confirmation of HME and HGA, even though the diagnosis is only retrospective. Antibody titers remain elevated for months to years after convalescence, and no evidence of persistent infection associated with clinical disease has ever been observed. Serologic cross-reactivity between *Ehrlichia* spp. and *Anaplasma phagocytophilum* is frequent, but differential titers can be helpful. No specific serologic tests exist for either HEE or EMLA. Most diagnoses of Panola Mountain ehrlichia and *Candidatus* N. mikurensis infections have been made by specific or broad-range PCR.

Laboratory criteria for *probable* HME and HGA include a compatible exposure history and clinical illness combined with (1) the detection of morulae in peripheral blood, (2) a single high positive IFA titer, or (3) positive PCR of acute phase blood. The criteria for a *confirmed* case of HME or HGA requires (1) demonstration of seroconversion (4-fold or greater change in serum antibody titer) with *E. chaffeensis* or *A. phagocytophilum*, (2) isolation of *E. chaffeensis* or *A. phagocytophilum* in culture from blood, or (3) a single elevated IFA titer combined with either detection of morulae in the peripheral blood smear or a positive PCR. Formal laboratory criteria for probable or confirmed HEE, EMLA or *Candidatus* N. mikurensis infection have yet to be established.

THERAPY

Ehrlichia and *Anaplasma* are susceptible in vitro to tetracycline, tetracycline derivatives, and rifampin. However, no controlled clinical trials of antimicrobial agent efficacy have been conducted and treatment recommendations are therefore based on the experience from empirical antibiotic treatment of infected humans. Even though HME and HGA can manifest as self-limited febrile illnesses that resolve spontaneously without therapy, it is currently recommended that any patient diagnosed with acute infection should receive antibiotic treatment. Doxycycline, 100 mg administered twice daily (oral or intravenous route), is the treatment of choice for adults. Doxycycline, 2 mg/kg, maximum dose 100 mg, given twice daily, is the preferred treatment for children who are seriously ill. The response to doxycycline is rapid; most patients become afebrile and resolve symptoms within 24 to 36 hours. In fact, failure to respond to doxycycline should prompt further clinical evaluation of the patient for an alternative diagnosis. The optimal duration of therapy with doxycycline has not been established. Serologic surveys demonstrate that 15% to 20% of patients with active HGA also are seroreactive with *B. burgdorferi*, the agent of Lyme borreliosis. Doxycycline therapy should therefore be administered for 10 to 14 days to ensure adequate coverage for potential co-incubating Lyme borreliosis.

Treatment with rifampin can be considered for pregnant women, known hypersensitivity to tetracycline class drugs, and children younger than 8 years with mild to moderate illness suitable for outpatient management. The dose of rifampin is 300 mg given twice daily for adults and 10 mg/kg (maximum dose 300 mg) twice daily for children for 5 to 7 days. Chloramphenicol is not recommended for treatment of ehrlichiosis, since in vitro susceptibility assays with chloramphenicol demonstrate poor activity against *E. chaffeensis* and *A. phagocytophilum*, and treatment failures with fatal outcome have been noted. Fluoroquinolones have in vitro activity against *A. phagocytophilum*, but not *E. chaffeensis*; however, limited experience has shown that levofloxacin is apparently not bactericidal and should not be used to treat HGA.

Human ehrlichioses are for the most part self-limited clinical illnesses that resolve spontaneously, even without active antibiotic therapy. Unlike Lyme borreliosis and babesiosis, HME, HEE, HGA, and EMLA have not been reported to be associated with persistent infection, but several patients with *Candidatus* N. mikurensis infection had severe febrile illnesses that lasted as long as several weeks before treatment or death. The long-term prognosis after resolved HME, HEE, HGA, and EMLA appears favorable, and patients should expect to make a complete recovery.

Christopher F. Carpenter and Nicholas Gilpin

Candida species are small unicellular yeasts that are found in a number of environments, including soil, hospital surroundings, food, and other inanimate objects. Most species are commensal organisms, colonizing the skin, gastrointestinal tract, and vagina. They become opportunistic pathogens when the host has compromised immunologic or mechanical defenses or when there are changes in the host's normal flora, such as those triggered by broad-spectrum antibiotic use and chemotherapy. *Candida* species are common causes of disease ranging from superficial cutaneous and mucocutaneous infections to invasive infections such as candidemia and disseminated candidiasis. There are more than 150 species of *Candida*, with *Candida albicans* (Figure 172.1) being the most frequently implicated in human disease processes. Over the past two decades, however, there has been a noticeable increase in disease due to non-*albicans* species. Important non-*albicans* pathogens include *Candida tropicalis* (Figure 172.2), *Candida parapsilosis*, *Candida glabrata* (Figure 172.3), *Candida krusei* (Figure 172.4), *Candida kefyr*, *Candida lusitaniae*, *Candida dubliniensis*, and *Candida gulliermondii*. Less commonly isolated species with medical significance include *Candida lipolytica*, *Candida famata*, *Candida rugosa*, *Candida viswanathii*, *Candida haemulonii*, *Candida norvegensis*, *Candida catenulate*, *Candida ciferri*, *Candida intermedia*, *Candida utilis*, *Candida lambica*, *Candida pulcherrima*, and *Candida zeylanoides*.

Diagnosis of *Candida* infections continues to be primarily via culture, although a number of faster

and more sensitive contemporary diagnostic methods have become available, including polymerase chain reaction (PCR), CHROMagar (Figure 172.5), and fluorescent *in situ* hybridization (FISH). Indirect diagnostic methods have also become more widely used in clinical practice, such as the serum or plasma (1→3)-β-D-glucan (BDG) assay, which is specific for a unique component of the cell wall in many fungi that is

Figure 172.4 *Candida krusei*. CHROMagar. (Courtesy of Dr. Barbara Robinson-Dunn and Ms. Mrudula Nandwana, Beaumont Health System.)

detectable during invasive candidiasis. Given that several *Candida* species have intrinsic or acquired resistance to antifungal agents (Table 172.1), these tests may prove to be cost-effective approaches for guiding early appropriate antifungal therapy in certain clinical settings. Newer antifungal agents have become available for the treatment of *Candida* infections, including advanced-generation triazoles and the echinocandins (Table 172.2), which are particularly useful when antifungal resistance is suspected or proven.

INFECTIOUS SYNDROMES AND TREATMENT/PROPHYLAXIS

Mucocutaneous *Candida* syndromes

CUTANEOUS CANDIDIASIS

Primary cutaneous candidiasis is commonly seen in normal hosts manifesting as diaper dermatitis and intertriginous infections. Other manifestations include balanitis, folliculitis, paronychia, and onychomycosis. Cutaneous candidiasis most commonly presents in skin areas that are moist and/or occluded, or in areas of impaired skin integrity, such as burns or chronic wounds. Immunocompromised patients, including patients with diabetes mellitus, are also at increased risk. Cutaneous candidiasis is generally a clinical diagnosis, demonstrated by the presence of a confluent erythematous rash with satellite lesions in a typical warm, moist environment such as the perineum or axilla. Microscopic

examination of skin scrapings revealing budding yeast cells and hyphae may be useful to confirm the diagnosis. Positive cultures for *Candida* species may also assist with diagnosis; however, positive results may occur because of colonization or contamination, and thus culture is generally not recommended. Bacterial superinfection may also coexist with cutaneous candidiasis, and sometimes necessitates antimicrobial therapy. Nonantimicrobial methods are important in both prevention and treatment of cutaneous candidiasis, such as keeping skin surfaces clean and dry, frequent diaper changes, and control of hyperglycemia in diabetics. Topical antifungals such as nystatin cream or an imidazole cream are the mainstay of treatment. Systemic therapy with fluconazole, itraconazole, or terbinafine is rarely required for severe or refractory cases.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Individuals with chronic mucocutaneous candidiasis suffer from persistent and recurrent *Candida* infections of the skin, nails, and mucous membranes. It most commonly occurs within the first two decades of life. T-cell dysfunction is the primary immunologic abnormality associated with chronic mucocutaneous candidiasis, although other immune abnormalities such as immunoglobulin deficiency and cutaneous anergy have been described. Several endocrine disorders have been associated with chronic mucocutaneous candidiasis, such as hypoparathyroidism, Addison's disease, hypothyroidism, and diabetes. The disease is a complex disorder that may manifest as one of many different syndromes with variable severity, although associated invasive disease is quite rare.

Therapy for mucosal infections is typically accomplished with topical or systemic triazole antifungal agents. A significant problem with mucosal disease is its propensity for repeated relapses, particularly among immunocompromised hosts and persons with human

immunodeficiency virus (HIV) infection. Chronic suppressive therapy is usually unnecessary, but occasionally employed in select cases, with the associated risk of emerging resistance.

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

As normal members of the gastrointestinal tract flora, *Candida* species become pathogenic in the oropharynx and esophagus in patients with various risk factors, including impaired cell-mediated immunity (e.g., HIV infection, chronic mucocutaneous candidiasis, stem cell and solid organ transplant recipients), diabetes mellitus, extremes of age, or esophageal motility disorders. The use of certain medications, including progesterone, broad-spectrum antibiotics, or immunosuppressive agents is also a contributing factor in many cases.

Oral candidiasis most commonly presents as creamy white plaque-like lesions on the oropharyngeal mucosa or tongue surface. Candidiasis lesions are typically painless, but atypical and more symptomatic forms may exist, such as erythematous or pseudomembranous plaques (erythematous candidiasis), *Candida* leukoplakia, or hyperplastic candidiasis. Angular chelitis, a painful condition with associated cracking and erythema at the oral commissure, can also be a result of *Candida* infection. As with cutaneous candidiasis, oropharyngeal candidiasis is usually a clinical diagnosis. Cultures are not usually recommended because of the potential for positive results due to colonization. For treatment of mild disease, clotrimazole troches or nystatin suspension for about 7 to 14 days are recommended first-line agents. For more moderate-to-severe oropharyngeal candidiasis, including patients with HIV infection, systemic therapy with low-dose oral fluconazole for 7 to 14 days is generally recommended. Infections that are refractory to fluconazole should be managed with another systemic antifungal agent, such as an extended-spectrum triazole or echinocandin.

Esophageal candidiasis often presents as dysphagia or odynophagia, usually with retrosternal pain. Clinically, it can be difficult to distinguish *Candida* esophagitis from other causes of esophagitis, such as cytomegalovirus esophagitis, herpes simplex virus esophagitis, esophageal ulcers, eosinophilic esophagitis, or pill esophagitis. The presence of oral thrush coupled with dysphagia or odynophagia has relatively good predictive value for esophageal candidiasis, and a therapeutic trial is a reasonable alternative to endoscopy in such patients. Empirical therapy should include a systemic antifungal for about 14 to 21 days; typically fluconazole in oral or parenteral form is prescribed. In rare circumstances, an alternative antifungal agent such as an echinocandin, extended-spectrum triazole, or low-dose amphotericin B may be required. In refractory cases, endoscopy with mucosal brushings or biopsy may be necessary to confirm the diagnosis, test for antifungal resistance, and evaluate for other potential concomitant pathogens or disorders (Figures 172.6 and 172.7).

VULVOVAGINAL CANDIDIASIS

Vulvovaginal candidiasis (VVC) is common in women of childbearing age and is the most common form of mucosal candidiasis. Several

Table 172.3 Classification of vulvovaginal candidiasis (VVC)

Uncomplicated VVC	Complicated VVC
All of the following: • Sporadic and infrequent VVC • Mild to moderate VVC • Likely to be *Candida albicans* • Nonimmunocompromised women	At least one of the following: • Recurrent VVC • Severe VVC • Non-*albicans* VVC • Women with uncontrolled diabetes mellitus, debilitation, or immunosuppression, or women who are pregnant

Source: Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2010. *MMWR Recomm Rep.* 2010;59(RR-12):1–110.

host risk factors can predispose to VVC, including pregnancy, oral contraceptive use, antibiotic use, diabetes mellitus, HIV infection, and the presence of an intrauterine device or a diaphragm. Many times no precipitating factor can be found. The mechanism by which asymptomatic colonization transforms into symptomatic VVC remains unclear. For clinical purposes, VVC may be classified as complicated or uncomplicated (Table 172.3). About 90% of cases are classified as uncomplicated. The clinical manifestations of VVC are primarily vulvar pruritus, vaginal discharge, dyspareunia, dysuria, and vaginal irritation, although none of these symptoms are particularly sensitive or specific. Signs include erythema and edema of the vulva with erythema of the vagina and vaginal discharge of variable consistency, often described as thick and curd-like. As with other forms of mucocutaneous candidiasis, the diagnosis is typically made clinically, but confirmation is easily obtained by observing budding yeast, with or without pseudohyphae, on a wet mount or 10% potassium hydroxide preparation of vaginal secretions. Evaluation for concomitant pathogens or sexually transmitted infections is also prudent.

Uncomplicated VVC can be managed successfully with a number of topical antifungal agents, with courses typically ranging from about 3 to 7 days. Alternatively, fluconazole as a single dose of 150 mg is also quite effective. Treatment with azoles results in symptomatic relief in about 80% to 90% of patients who complete therapy, and no agent is considered clearly superior.

Complicated VVC, including recurrent VVC (RVVC, usually defined as four or more episodes of symptomatic VVC in 1 year), affects a small percentage of women (≤5%). Vaginal cultures should be obtained to confirm the clinical diagnosis of RVVC and to identify unusual species, including non-*albicans* species such as *C. glabrata*, for which conventional antifungal therapies may not be as effective. Each individual episode of RVVC caused by *C. albicans* usually responds well to short-duration oral or topical azole therapy, but in some situations a course of induction therapy followed by a maintenance dose of suppressive antifungal therapy for several months is necessary for control of symptoms. Unfortunately, 30% to 50% of women will have recurrent disease after suppressive therapy is discontinued. For pregnant patients with VVC, topical therapy is recommended.

Candidemia and disseminated candidiasis

CANDIDEMIA

Candida species are a significant cause of nosocomial bloodstream infections in the United States. Crude mortality rates of candidemia range from 30% to 61% with attributable mortality ranging as high as 49%. *Candida* species, like some bacterial pathogens, are capable of forming biofilms on catheters and other surfaces, leading to infections that are difficult to eradicate. Certain risk factors are known to predispose to candidemia, but it remains very difficult to clinically predict which patients will develop infection. For example, colonization with yeast remains a leading risk factor for infection in the intensive care unit (ICU). However, the prevalence of colonization in the ICU is high (50%–70% or more), which corresponds to a low predictive value given the relatively low rate of invasive infection. Nevertheless, colonization in ICU patients with unexplained fever, leukocytosis, and hypotension merits strong consideration of invasive candidiasis and candidemia as a potential cause of sepsis. Delay of antifungal treatment portends significantly high mortality. In all cases, candidemia requires antifungal treatment and removal of potential sources, such as vascular devices. Search for additional foci of infection is also critical, as dissemination to areas such as the eye, liver, spleen, kidney, heart, soft tissues, bone, central nervous system (CNS), and gastrointestinal tract may occur. This is of particular concern in patients who are immunocompromised.

Empiric therapy for suspected invasive candidiasis should include a triazole or echinocandin. *Candida albicans* is usually susceptible to most antifungals, including fluconazole, whereas other species are more likely to demonstrate reduced

susceptibility or resistance to select antifungals. For example, *C. krusei* is intrinsically resistant to fluconazole and itraconazole but is usually susceptible to the extended-spectrum triazoles, echinocandins (nearly 100% susceptible), and amphotericin B formulations (though higher doses may be required). *Candida glabrata* has variable dose-dependent susceptibility to fluconazole and itraconazole, and it may be frankly resistant to these antifungals. It also typically shows some degree of cross-resistance to the newer triazoles, although both voriconazole and posaconazole are usually effective. The echinocandins have activity against most *Candida* species, although *C. parapsilosis* typically has relatively higher minimum inhibitory concentrations to these antifungals. The clinical relevance of these in vitro data is not clear.

For non-neutropenic patients, potential antifungal choices include fluconazole (800 mg [12 mg/kg] loading dose, followed by 400 mg [6 mg/kg] per day), caspofungin (70 mg loading dose followed by 50 mg/day), micafungin (100 mg/day), or anidulafungin (200 mg loading dose followed by 100 mg/day). Amphotericin B or a lipid-based amphotericin B formulation is an alternative that is much less commonly used for this indication today, generally only if there is intolerance to the other antifungal agents. For stable patients or those without prior azole exposure, fluconazole is reasonable for empiric therapy. Critically ill or hemodynamically unstable patients should be started on an echinocandin rather than fluconazole. Most neutropenic patients should initially be managed with an echinocandin. Select circumstances may lead to use of a lipid-based amphotericin B formulation, fluconazole, or voriconazole. Fluconazole and amphotericin B are considered alternatives due to concerns for potential resistance and toxicity, respectively. All candidemia treatment should be extended for at least 2 weeks after clearance of candidemia and resolution of sepsis. For neutropenic patients, recovery of neutrophil counts is another important factor, and antifungal treatment should generally be continued until this occurs.

CHRONIC DISSEMINATED CANDIDIASIS

Chronic disseminated candidiasis (CDC, formerly hepatosplenic candidiasis) is an indolent process most commonly found in patients with severe persistent neutropenia (e.g., in patients with acute leukemia or stem cell transplant recipients) that frequently becomes apparent when the neutrophil count begins to recover. It typically involves the liver and/or spleen, although other organs may be involved. Computed tomography (CT) or magnetic resonance imaging (MRI) studies are helpful in confirming the diagnosis (>90% sensitive), often by identifying small discrete lesions within the liver or spleen. Unfortunately, such lesions may be absent early in the course of disease. Signs and symptoms of CDC are neither sensitive nor specific, and may include right upper quadrant tenderness, elevated transaminases and alkaline phosphatase concentrations, and hepatosplenomegaly. Blood cultures are often negative, and biopsy may be required to confirm the diagnosis. Much of what is known about treatment of CDC has been gathered from case-series data. Amphotericin B, fluconazole, and echinocandins have been shown successful. Therapy should be continued until lesions appear calcified or cleared, a process which may take several months. Notably, in patients who receive repeated courses of antineoplastic therapy or who persistently remain immunosuppressed, prolonged treatment or suppression may be necessary.

Other forms of invasive candidiasis

ENDOCARDITIS AND CARDIAC DEVICE INFECTIONS

Patients with *Candida* endocarditis and patients with bacterial endocarditis share both risk factors (intravenous drug use, cardiac surgery, prosthetic heart valves, abnormal native heart valves, and central venous catheters) and clinical presentation (fever, nonspecific signs and symptoms, cardiac murmur, and congestive heart failure). Mycotic emboli to major arteries are more common in *Candida* endocarditis, and blood cultures are often negative initially. The diagnosis should be considered in all patients with candidemia. Evidence of a valvular vegetation by transthoracic or the more sensitive transesophageal echocardiogram establishes the diagnosis. Definitive treatment for native or prosthetic valve *Candida* endocarditis involves valve replacement in conjunction with a prolonged course of antifungal therapy, typically lipid-based amphotericin B formulation (3–5 mg/kg/day with or without flucytosine 25 mg/kg four times daily) for at least 6 weeks. Alternatives include amphotericin B or higher doses of an echinocandin. Chronic suppression with fluconazole is recommended if valve replacement cannot be performed and the yeast is susceptible. Following treatment, patients should be monitored

closely for a minimum of 1 year due to the propensity for relapse.

Infections due to *Candida* species involving cardiac devices such as pacemaker and implantable cardiac defibrillator infections are fortunately uncommon. Therapy should include removal of the entire device as well as systemic antifungal therapy as recommended for endocarditis. If the infection is limited to the generator or pocket, 4 weeks of therapy is recommended. If the infection involves wires or leads, at least 6 weeks of therapy is recommended. Failure to remove the device completely should warrant long-term suppressive azole therapy.

CENTRAL NERVOUS SYSTEM INFECTIONS

Meningitis is the most common form of CNS candidiasis, but numerous other forms of infection such as cerebral or epidural abscesses may occur. Low-birth-weight infants and immunosuppressed hosts are at particularly increased risk for meningitis. Nosocomial risk factors such as recent neurosurgery and the presence of ventricular shunts and drains are also significant in the development of *Candida* CNS infections. Signs and symptoms are similar to, but often less severe than, bacterial meningitis. Typically there is a more indolent and chronic course. Cerebrospinal fluid (CSF) analysis usually reveals a neutrophilic predominance, elevated protein, and either normal or depressed glucose. The diagnosis can be difficult because the organism is present in low numbers in the CSF and the yield of standard CSF cultures is poor; thus repeated CSF cultures may be required. Combination therapy with lipid-based amphotericin B (3–5 mg/kg/day) plus flucytosine (25 mg/kg four times daily) is recommended initially. After there is clinical response to initial therapy (usually several weeks later), treatment may be adjusted to fluconazole (400–800 mg/day) until all signs and symptoms have resolved. Removal of any ventricular shunt or drain is highly recommended to achieve eradication.

OCULAR INFECTIONS

Up to 15% of patients with candidemia have retinal lesions, often visible within 1 week of the onset of illness. The mortality rate in ICU patients with *Candida* endophthalmitis is considerably higher than the mortality rate in patients with candidemia alone. Symptoms may include bulbar pain, scotomas, and blurred vision. Diagnosis requires a high degree of clinical suspicion, and thus all patients with candidemia should be screened at least once for endophthalmitis by an ophthalmologist. Additional screening is discretionary, and may be required in cases of persistent candidemia or in patients who are unable to communicate regarding visual disturbances. Lesions may be sight-threatening; diagnosis relies on characteristic ocular findings such as white lesions on the retina with ill-defined borders with possible vitreal extension. A diagnostic vitreal aspiration is often necessary if endophthalmitis is suspected and the etiology is unknown. The sensitivity of vitreous humor cultures remains low, ranging from 33% to 50%. Recommended systemic therapy for endophthalmitis includes an amphotericin B formulation with or without flucytosine at doses used for candidemia, particularly for sight-threatening lesions. Fluconazole or voriconazole are other treatment options. Both have good vitreal penetration and less toxicity compared with amphotericin B. Caution is advised with the use of echinocandins because of poor ocular tissue penetration. Typically, about 4 to 6 weeks of therapy is anticipated for endophthalmitis in conjunction with close ophthalmology follow-up. Vitrectomy with intravitreal amphotericin B should be considered for severe endophthalmitis, vitritis, or evidence of progression or an absence of response.

GASTROINTESTINAL CANDIDIASIS

Candida peritonitis may develop in patients on peritoneal dialysis, after gastrointestinal surgery, as a complication of candidemia, or as an extension of local organ or tissue infection. In addition, gastric and duodenal mucosal infections may develop in patients with peptic ulcer disease or mucosal neoplasm. Other rare intra-abdominal manifestations of *Candida* infection include isolated pancreatic abscess, gangrenous cholecystitis, and obstruction of the common bile duct with a *Candida* fungus ball. *Candida albicans* is the predominant species isolated in intra-abdominal infections, but *C. glabrata* plays a significant role. Diagnosis is made by paracentesis or by endoscopic, percutaneous, or open biopsy. Antifungal therapy targeting *Candida* is not recommended for all patients with community-acquired intra-abdominal infection, but antifungal therapy is recommended in patients with severe infection or healthcare-associated intra-abdominal infection. An echinocandin or fluconazole is most commonly recommended for empiric therapy. Amphotericin B formulations are not usually recommended due to significant toxicity. As with all intra-abdominal infections, appropriate source

control measures (e.g., drainage of abscesses, removal of infected material, etc.) are also crucial in management.

BONE AND SOFT-TISSUE INFECTION

Bone and soft-tissue infections are rare complications of *Candida* dissemination or direct extension of a local *Candida* infection and are diagnosed by needle aspiration or via surgical debridement. They also may result from exogenous inoculation during trauma, intra-articular injection, a surgical procedure, or injection drug use. Treatment usually requires a combination of surgical debridement and often prolonged systemic antifungals, and high-dose fluconazole or a lipid-based amphotericin B formulation should be considered for initial therapy; extended-spectrum triazoles and echinocandins may have a role as well, but few data are available. Treatment is recommended for at least 6 to 12 months in cases of osteomyelitis, and about 6 weeks in cases of septic arthritis and bursitis. If prosthetic joint hardware or other devices are involved, removal is highly recommended to achieve cure.

RESPIRATORY TRACT CANDIDIASIS

Pneumonia due to *Candida* spp. is exceedingly rare as an isolated *Candida* infection. It is also poorly defined as a clinical entity because positive cultures cannot distinguish between true infection and either colonization or contamination of samples with oropharyngeal contents. Confirming a diagnosis of *Candida* pneumonia requires histopathologic confirmation, which is rarely performed. Growth of *Candida* from respiratory secretions alone is insufficient to warrant therapy and perhaps best serves to document colonization.

Patients with empyema due to *Candida* generally have an underlying predisposing condition such as malignancy, and esophageal perforation should be considered in patients at risk. Most cases are nosocomially acquired, occurring frequently with concomitant bacterial infection. Diagnosis is made with isolation of a fungal species from an exudative pleural effusion in association with clinical signs of infection. Treatment via drainage and systemic antifungals with an amphotericin B formulation or fluconazole is appropriate. The newer triazoles and echinocandins also may be considered, but data are limited.

GENITOURINARY *CANDIDA* INFECTIONS

The isolation of *Candida* in the urine is common in hospitalized or nursing home patients, especially in those with indwelling urinary catheters. Most often catheter-related candiduria is asymptomatic, and although it generally does not require antifungal treatment, it may occasionally be difficult to distinguish patients with asymptomatic candiduria from those with true *Candida* urinary tract infections. Infections are more common and potentially more serious in patients who are taking broad-spectrum antibiotics or immunosuppressive agents, in patients with diabetes mellitus or who are otherwise immunosuppressed, and in patients with genitourinary abnormalities (including obstructive uropathy and renal transplant recipients). The diagnosis is problematic, as high colony count is not a strong indicator of infection, and pyuria in this setting is not always helpful. Frequently, the clinical suspicion combined with signs and symptoms of infection and culture results post removal of the catheter may be all that is available for the clinician. In most episodes of candiduria, catheter removal is often all that is required. *Candida* infection of the bladder also must be distinguished from infection of the kidney, although the two entities can coexist. Invasive infection of the kidney is unusual and is more difficult to treat. Other genitourinary syndromes (e.g., epididymo-orchitis) often require percutaneous culture for diagnosis.

Antifungal treatment for candiduria is recommended if symptoms of urinary tract infection are present, for patients with neutropenia, for low-birth-weight infants, for renal transplant recipients, or for patients undergoing urologic procedures. Fluconazole is appropriate initial therapy, because it is well tolerated and achieves good levels in the urinary tract. If fluconazole resistance is suspected, systemic amphotericin B is an appropriate treatment alternative. Amphotericin B bladder irrigations are not routinely recommended due to high relapse rates, and other systemic antifungals (e.g., the echinocandins, posaconazole, and voriconazole) do not achieve adequate urine levels to be considered optimal for treatment.

173. Aspergillosis

Sanjay Ram and Stuart M. Levitz

Aspergillus is readily isolated from environmental samples of soil, water, and air worldwide. *Aspergillus fumigatus*, followed by *Aspergillus flavus*, *Aspergillus niger*, and *Aspergillus terreus*, are the most common species that cause human disease. Aspergillosis follows exposure of a susceptible host to the ubiquitous conidia (spores). Germinating conidia form hyphae, the invasive form of the fungus. *Aspergillus* hyphae average 2 to 4 μm in diameter and are septate, with dichotomous (Y-shaped) branching (Figure 173.1). The spectrum of diseases caused by the aspergilli is wide and profoundly influenced by the underlying immune status of the host.

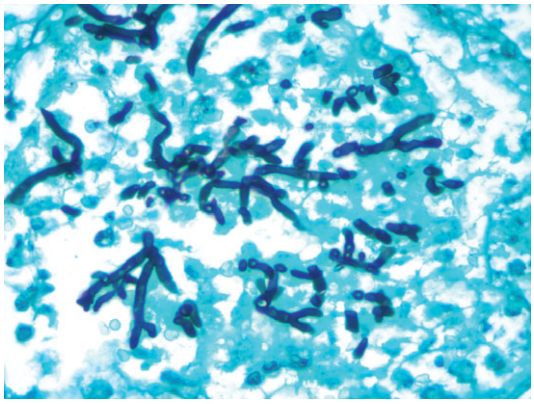

Figure 173.1 Photomicrograph demonstrating *Aspergillus* hyphae in a lung at autopsy in a liver transplant patient who died of systemic aspergillosis. The hyphae are stained with methenamine silver. (Courtesy of Dr. Barbara Banner, University of Massachusetts Medical School.)

CLINICAL MANIFESTATIONS AND DIAGNOSIS OF INVASIVE ASPERGILLOSIS

Although inhalation of conidia is common, invasive disease is relatively rare. The vast majority of affected patients are severely immunosuppressed. Major risk factors include prolonged neutropenia and macrophage dysfunction secondary to cytotoxic chemotherapy and high doses of corticosteroids, respectively. In patients who have undergone hematopoietic stem cell transplantation, additional risk factors are graft-versus-host disease and cytomegalovirus infection. Invasive aspergillosis also is particularly common in individuals with chronic granulomatous disease, a rare genetic disorder characterized by a defective phagocyte respiratory burst. Finally, critically ill patients appear to be at risk for invasive aspergillosis, even without aforementioned risk factors.

Invasive pulmonary aspergillosis, with or without dissemination, is the most common form of disease. Signs and symptoms of invasive aspergillosis are nonspecific. Fever is generally present. Radiographic features include patchy densities or well-defined nodules that may be single or multifocal and can progress to cavitation or consolidation. High-resolution computed tomography (CT) scanning has greater sensitivity than plain films. Macronodules (nodules greater than 1 cm in diameter) are present in the vast majority of patients with invasive pulmonary aspergillosis. Nodules may be surrounded by a perimeter of ground-glass opacity, the so-called halo sign (Figure 173.2). Cavitation ("air-crescent sign") is less common and tends to occur as a later manifestation of disease. Tracheobronchitis without alveolar invasion may be seen, particularly in lung transplant recipients and those with advanced acquired immunodeficiency syndrome (AIDS). Invasive *Aspergillus* sinusitis is the second most common manifestation and must be distinguished from saprophytic colonization. Its clinical features include fever, localized pain, proptosis, and visual problems. Fungal keratitis due to direct inoculation of *Aspergillus* has been increasingly recognized as an important cause of visual loss, particularly among agrarian workers in developing countries. Less common manifestations include cutaneous aspergillosis, which may be seen at intravenous catheter insertion sites in neutropenic patients or at sites of burn

wounds. While disseminated aspergillosis can involve any organ, cerebral involvement is a particularly common manifestation. Endocarditis due to *Aspergillus* is relatively rare and can be difficult to diagnose as blood cultures are often negative.

Invasive aspergillosis must be strongly suspected in any high-risk patient with fever unresponsive to broad-spectrum antibiotics, and empiric antifungal therapy should be considered. Although *Aspergillus* can be a laboratory contaminant or a colonizer, a positive culture for *Aspergillus* in an at-risk patient is predictive of invasive disease and should not be ignored. However, in patients with established disease, cultures and even biopsies are often negative.

In an effort to improve prognosis with earlier detection, nonculture methods to detect *Aspergillus* antigens and nucleic acids in specimens from high-risk patients have been studied. Tests to detect two cell wall antigens released by growing aspergilli, galactomannan and β-glucan, are clinically available. Serum galactomannan levels have excellent specificity but only moderate sensitivity. Sensitivity is higher in patients with hematologic malignancies, where positive results may precede clinical or radiologic manifestations, than in those with solid organ transplants. False positives have been noted in patients receiving piperacillin–tazobactam and amoxicillin–clavulanate due to contamination of some lots with galactomannan. False negatives are considerably more common in patients receiving antimold prophylaxis. Assays to detect β-glucans in clinical specimens appear to perform comparably to those for galactomannan, with the caveat that elevated β-glucans may be seen in fungal infections besides aspergillosis. Tests to detect *Aspergillus* DNA and RNA in clinical samples remain investigational. It should be emphasized that the aforementioned surrogate detection markers cannot definitively establish or exclude a diagnosis of aspergillosis and clinical correlation is required. Moreover, testing for antibodies, while useful for other forms of aspergillosis (see below), is not helpful in invasive aspergillosis.

TREATMENT OF INVASIVE ASPERGILLOSIS

Licensed drugs with activity against *Aspergillus* include amphotericin B (a polyene); the triazoles, itraconazole, voriconazole, and posaconazole; and the echinocandins, caspofungin, micafungin, and anidulafungin. Fluconazole and ketoconazole do not inhibit *Aspergillus* at clinically obtainable concentrations and should not be used to treat aspergillosis. It is somewhat difficult to rank the active drugs in terms of relative efficacy because few randomized comparative trials have been performed. Studies based on comparisons to historical controls are problematic due to significant differences in the patient populations. A multicenter, randomized trial compared voriconazole with amphotericin B in 277 patients with definite or probable acute invasive aspergillosis. The voriconazole regimen demonstrated superior efficacy and a 22% relative survival benefit. Moreover, there were fewer treatment-related adverse events in the voriconazole group. This study was criticized for its unblinded design, the use of conventional (rather than lipid-based) amphotericin B preparations, and the allowance

of a switch to other licensed antifungal medications. Nevertheless, the large survival benefit observed established voriconazole as the drug of choice for initial treatment of invasive aspergillosis. An important caveat though is voriconazole is not effective therapy against zygomycosis, which can present in a similar manner to aspergillosis.

In the above study, two doses of 6 mg/kg of intravenous voriconazole were administered on day 1, followed by 4 mg/kg/day. A switch to oral voriconazole at a dose of 200 mg twice a day was allowed after 1 week. Transient visual disturbances, including blurred vision, altered color perception, and photophobia, are common with voriconazole and tend to resolve without incident. Other side effects that have been observed include rash and liver function test abnormalities. Voriconazole is a substrate and an inhibitor of CYP2C19, CYP2C9, and CYP3A4. Thus, drug interactions are common and dose adjustments of voriconazole and coadministered drugs may be needed. The authors recommend obtaining steady-state trough levels and adjusting the dosing if necessary to achieve levels between 1.0 and 5.5 μg/mL. In patients with an estimated creatinine clearance <50 mL/min, accumulation of the intravenous vehicle occurs; these patients should be given oral voriconazole whenever possible.

In addition to voriconazole, other licensed triazoles with activity against *Aspergillus* are itraconazole and posaconazole. Itraconazole appears to be least potent and is mainly used for the treatment of aspergillomas and allergic bronchopulmonary aspergillosis (see below). Posaconazole appears more promising and has the added advantage of having useful activity against zygomycetes, but clinical experience with its use for primary treatment of invasive aspergillosis is limited. Delayed-release tablets and an IV formulation of the drug recently became available. Resistance of *Aspergillus* to voriconazole and other triazole drugs can emerge during therapy although the extent to which this leads to clinical failure is not clear. Ominously, primary resistance has been increasingly reported in both environmental and initial clinical isolates of *Aspergillus*, perhaps as a consequence of the agricultural use of azoles.

Amphotericin B is generally used for the treatment of invasive aspergillosis in patients who cannot take voriconazole because of contraindications or intolerance. (Amphotericin B should not be used to treat *Aspergillus terreus* or *Aspergillus nidulans* due to decreased susceptibilities.) However, controversy exists regarding the optimal daily dosage and formulation. For the conventional amphotericin B desoxycholate formulation, following a test dose of 1 mg, dosages ranging from 0.6 to 1.5 mg/kg/day have been recommended, with higher dosages reserved for severely ill and/or profoundly immunosuppressed patients. Fevers, chills, and rigors, observed in a significant number of patients treated with amphotericin B, may be alleviated by premedication with acetaminophen, meperidine, 25 to 50 mg given intravenously, or the addition of 25 to 50 mg of hydrocortisone sodium succinate to the infusion solution. Amphotericin nephrotoxicity has been associated with sodium-depleted states and may be reduced by giving 1 L of normal saline a day to patients with no contraindications to volume expansion. As amphotericin B causes renal tubular losses of potassium and magnesium, their levels should be monitored closely and supplementation provided as needed. The dosage of amphotericin B must be individualized depending on factors such as the expected duration and degree of immunosuppression, and the extent of the disease.

In an effort to reduce the toxicity associated with the conventional amphotericin B preparation, lipid-associated formulations have been developed. Currently available formulations include amphotericin B lipid complex, amphotericin B colloidal dispersion, and a liposomal preparation. Comparisons between the different formulations of amphotericin B are difficult to make due to the lack of well-designed randomized trials. However, at the usual daily dosages recommended for the treatment of invasive aspergillosis (3 to 5 mg/kg/day), the lipid formulations appear to be at least as efficacious as amphotericin B deoxycholate. The lipid formulations are less nephrotoxic than the conventional preparation but cost considerably more. A clinical trial comparing 3 and 10 mg/kg/day of liposomal amphotericin B as primary therapy for invasive aspergillosis found the lower dose was equally effective but less toxic.

Three members of the echinocandin class of antifungal drugs, caspofungin, micafungin, and anidulafungin, are licensed for use. All have modest activity against *Aspergillus* in vitro and in animal models, although none has been adequately studied in comparative clinical trials for primary treatment of invasive aspergillosis. In an open-label study of 83 patients with invasive aspergillosis who were refractory or intolerant to amphotericin B, a favorable response to

caspofungin therapy was observed in 37 (45%) of the subjects. Due to poor oral absorption, the echinocandins must be administered intravenously. Although infusion-related reactions and liver function test elevations are relatively common, serious side effects of this class of drugs are rare.

Due to the high failure rate associated with monotherapy for invasive aspergillosis, combination regimens as initial and salvage therapy have been tried. A randomized, double-blind study comparing voriconazole and anidulafungin combination therapy with voriconazole monotherapy in the treatment of invasive aspergillosis was recently completed. As of this writing, the results had not yet been published in a peer-reviewed journal. However, an analysis of the data revealed a trend, which did not reach statistical significance, towards improved overall survival in the group that received combination therapy. It is the authors' practice to treat most cases of invasive aspergillosis with voriconazole monotherapy, but to add an echinocandin if progression results.

Regardless of whether monotherapy or combination therapy is utilized, the duration of treatment should be individualized depending on the extent of disease and degree of immunosuppression. Most patients will require several months of treatment. Surgery should be considered as an adjunct to treatment in instances where there is localized disease, particularly in cases where there is progression despite antifungal therapy or further courses of neutropenia-inducing chemotherapy are anticipated. Whenever possible, immunosuppression should be withdrawn or decreased. In neutropenic patients, recombinant granulocyte colony-stimulating factor (G-CSF) may improve outcome by decreasing the duration of neutropenia and increasing the functional activity of neutrophils. Finally, patients with filamentous fungal keratitis should be treated with 5% natamycin eyedrops initially applied every hour. Surgical intervention by ophthalmology is often required.

PROPHYLAXIS AND PRE-EMPTIVE TREATMENT OF INVASIVE ASPERGILLOSIS

Given the high mortality associated with established disease, strategies for the prevention of invasive aspergillosis have been advocated and are summarized in Table 173.1. Numerous studies have examined empiric antifungal therapy in neutropenic patients with persistent or recurrent fevers despite empiric antibacterial therapy. This group is at high risk for invasive fungal infections, particularly aspergillosis and candidiasis, but also other opportunistic mycoses, including zygomycosis and fusariosis. Thus, ideal agents will have activity against a broad spectrum of opportunistic fungi. However, for those for whom the duration of neutropenia is expected to be short, candidiasis is the main concern, with aspergillosis and other mold infections being less common.

The earlier studies, published in the 1980s, established that amphotericin B deoxycholate could decrease the incidence of invasive fungal infections in patients with persistent neutropenic

Table 173.1 Prevention of invasive aspergillosis

Preventive strategy	Comments
1. Avoidance of exposure to *Aspergillus* conidia a. Avoidance of environmental exposure b. High-efficiency particulate air (HEPA) filters or laminar air flow (LAF)	Heavily contaminated areas include compost heaps, grain silos, moldy hay, and marijuana Although expensive, HEPA and LAF may be considered for hospitalized patients at very high risk of invasive aspergillosis, particularly if mold counts are high
2. Prophylaxis of high-risk patients	Posaconazole or other mold-active antifungals should be considered in very high-risk groups[a]
3. Administration of colony-stimulating factors to neutropenic patients	Expensive. May be considered as part of an overall strategy to reduce infections in selected patients
4. Pre-emptive, empirical administration of antifungals to neutropenic patients with fevers despite broad-spectrum antibacterial agents	Strongly recommended[a]
5. Secondary prophylaxis (antifungal treatment to prevent recrudescence of invasive aspergillosis in patients who will become immunosuppressed)	Due to high relapse rates, voriconazole or amphotericin B should be given at the onset of chemotherapy or neutropenia. Consider surgical resection of localized disease[a]

[a] See text for details.

fevers. Subsequent noninferiority studies compared amphotericin B (either deoxycholate or lipid-based formulations) with fluconazole, itraconazole, voriconazole, and caspofungin. An important caveat in interpreting these studies is the variability in inclusion criteria and end points defining success. Fluconazole has been successfully used in patient populations at low risk of invasive aspergillosis. Itraconazole and caspofungin have demonstrated noninferiority compared with amphotericin B. In a large study comparing voriconazole with liposomal amphotericin B, there were fewer breakthrough fungal infections in the voriconazole group, though the study design has been criticized.

A study compared posaconazole (200 mg three times daily) with either fluconazole (400 mg/day) or itraconazole (200 mg/day) in 602 patients undergoing intensive chemotherapy for acute myelogenous leukemia or myelodysplastic syndrome. Patients received antifungal medications with each cycle of chemotherapy until complete remission or for up to 12 weeks. Remarkably, during the treatment phase of the study, only 2 cases of aspergillosis were seen in the posaconazole arm compared with 20 in the fluconazole–itraconazole arm. Moreover, there was a significant overall survival benefit in favor of posaconazole. Similarly, a significant reduction in cases of aspergillosis and in mortality was seen in a study comparing posaconazole with fluconazole for allogeneic hematopoietic stem cell transplant recipients with graft-versus-host disease.

ASPERGILLOMAS

Pulmonary aspergillomas are the result of saprophytic colonization of *Aspergillus*, usually within pre-existing lung cavities such as might result from sarcoidosis or tuberculosis. The diagnosis is most often made by chest radiography, where a round to oval intracavitary mass partially surrounded by a radiolucent crescent of air is seen. Serum precipitins and sputum cultures for *Aspergillus* are positive in about 90% and 50% of cases, respectively. Hemoptysis is the most common symptom, and in most cases is mild and self-limited. Rarely, extrapulmonary aspergillomas can form, particularly in the sinuses.

Therapy for aspergillomas must be individualized according to the pulmonary and immunologic status of the host, but in most cases a conservative approach with close clinical follow-up is recommended. Resection generally is reserved for those with life-threatening hemoptysis. However, many patients are not surgical candidates due to poor baseline lung function. Bronchial artery embolization can be tried as a temporizing measure for massive hemoptysis in patients with a high operative risk. Other measures, including intracavitary instillation of amphotericin B, oral itraconazole, and oral voriconazole, have been associated with reduction in cavity size and severity of hemoptysis in case reports. In one series of 40 patients, all patients had short-term resolution of hemoptysis following instillation of a locally formulated paste consisting of amphotericin B, fatty acids, and emulsifying wax.

A subset of patients with aspergillomas tends to be chronically ill, with fever, weight loss, pulmonary symptoms, and leukocytosis. This entity, termed "chronic necrotizing pulmonary aspergillosis," is seen in patients with chronic pulmonary disorders and mild systemic immunocompromise such as in diabetes mellitus, alcoholism, low-dose corticosteroids, or malnutrition. Whenever possible, host defenses should be strengthened by diminishing factors responsible for immunosuppression. Other patients have "chronic cavitary pulmonary aspergillosis" characterized by progressive expansion of *Aspergillus*-infected pulmonary cavities in the absence of known immunocompromise. With both entities, dramatic clinical responses have been observed in some patients following a course of antifungal therapy as is given for invasive aspergillosis. Resection may be considered in the small subset of patients with focal disease whose pulmonary function and underlying disease do not preclude surgery.

ALLERGIC MANIFESTATIONS OF *ASPERGILLUS*

Extrinsic allergic alveolitis occurs in nonatopic individuals who are exposed to *Aspergillus* conidia, as in "malt-worker's lung" or "farmer's lung," following their exposure to moldy grain or hay. Spontaneous recovery usually occurs over several weeks, without the need for corticosteroids. Exposure to *Aspergillus* in individuals with asthma can result in an exacerbation of their disease (extrinsic asthma).

Allergic bronchopulmonary aspergillosis (ABPA) is a syndrome characterized by asthma, proximal bronchiectasis, immediate cutaneous reactivity to *Aspergillus*, elevated serum immunoglobulin E (IgE) concentrations, and elevated

serum immunoglobulin G (IgG) and IgE antibodies specific to *A. fumigatus*. An increase in T_H2 CD4+ cells that respond to *Aspergillus* antigens and generate interleukin (IL)-4, -5, and -13 may contribute to the eosinophilia and high IgE levels seen in ABPA. Pulmonary infiltrates, peripheral eosinophilia, serum precipitins against *Aspergillus* antigens, and expectoration of fungus-laden mucus plugs may also be seen. Major predisposing factors are asthma and cystic fibrosis.

The goals of therapy are to reduce acute inflammation and minimize long-term lung damage. For patients with ABPA and pulmonary infiltrates, the primary treatment is prednisone in doses of 0.5 to 1.0 mg/kg/day for 1 to 2 weeks, followed by an alternate-day regimen and then a gradual taper over a 3- to 6-month period. Total IgE levels in the serum directly correlate with disease activity and response to corticosteroids. In clinical trials, itraconazole in doses of 200 mg twice daily was associated with fewer exacerbations, improved immunologic parameters, and a reduced requirement for corticosteroids. The salutary effects of itraconazole are likely to be primarily due to its antifungal activity. However, some of the responses could be due to inhibition of corticosteroid metabolism by itraconazole. Although it has not been well studied in randomized trials, based on its superiority in invasive aspergillosis voriconazole is increasingly being used in the treatment of ABPA.

Currently, two oral formulations of itraconazole are available: capsules and an oral aqueous acidified solution in 5% hydroxypropyl-β-cyclodextrin. Absorption of the capsular form is best in an acidic environment, and in the presence of a meal. Histamine-2 blockers and antacids may interfere with absorption. In contrast, the oral aqueous hydroxypropyl-β-cyclodextrin solution should be taken without food. This preparation achieves peak serum concentrations about 60% higher than the capsules but is more expensive and is associated with a higher incidence of gastrointestinal side effects. Drugs that induce hepatic microsomal enzymes (e.g., rifampin, isoniazid, phenytoin, phenobarbital, and carbamazepine) may significantly reduce serum itraconazole levels. Itraconazole itself slows hepatic drug metabolism and may increase the toxicity of phenytoin, oral hypoglycemics, digoxin, warfarin, and cyclosporine. Plasma concentrations of itraconazole can be measured in patients for whom absorption or drug metabolism problems are suspected, although therapeutic levels have not been established.

Allergic *Aspergillus* sinusitis often responds to endoscopic surgical debridement and drainage, particularly when there are obstructive symptoms. Intranasal corticosteroids may provide symptomatic relief but long-term use should be avoided as it can be detrimental to the nasal mucosa. There are anecdotal reports that itraconazole may be of benefit in refractory cases.

174. Mucormycosis (and entomophthoramycosis)

Scott F. Davies

The term mucormycosis refers to a group of highly lethal angioinvasive fungal infections, mostly in immunocompromised hosts, caused by members of the order Mucorales, which include various species of the genera *Rhizopus*, *Lichtheimia* (formerly *Absidia*), *Mucor*, and *Saksenaea*. Other genera of Mucorales have also been implicated in human disease including *Cunninghamella*, *Apophysomyces*, and *Rhizomucor*. Most infections (50%–65% of total) are caused by *Rhizopus* species.

Classification is in flux because of extensive molecular phylogenetic analysis that has been ongoing for more than 10 years. Note that it is incorrect to use the term mucormycosis to refer only to infections caused by species of the genus *Mucor*, which are only a small minority of the total number of cases. Rather, mucormycosis refers to infection by any of the organisms within the seven genera of the order Mucorales as noted.

The term entomophthoramycosis refers to infections by members of the separate genera *Conidiobolus* and *Basidiobolus*. These organisms generally occur in tropics and cause chronic subcutaneous infection mostly in immunocompetent hosts. Only rarely (less than 15 reported cases) have they ever caused clinical syndromes overlapping with mucormycosis.

For the remainder of this chapter the term mucormycosis will be used to refer to the range of clinical infections caused by organisms in the seven genera of the order Mucorales. In recent usage this term is generally preferred over the term zygomycosis, because of elimination of Zycomycetes from the taxonomic structure and the very different clinical syndrome as compared to entomophthoramycosis with virtually no clinical overlap.

PATHOGENESIS

The causative agents of mucormycosis are found throughout the world, associated with decaying organic matter. They grow as a mycelium (broad nonseptate hyphae with short stubby right-angle branches) in nature and in infected mammalian tissue.

Airborne spores of the fungi settle on the skin or are inhaled into the nose, the pharynx, and the lung. The organism has little chance of invading healthy tissue defended by neutrophils. *Rhizopus* organisms grow best at acid pH in a high-glucose environment. A specific enzyme, ketone reductase, plays an important role. Thus diabetic ketoacidosis provides a favorable opportunity for the fungus to locally invade tissues of the upper airway, resulting in the fulminant rhinocerebral form of mucormycosis. Once established, the fungus is angioinvasive, leading to infarction of tissues and wider areas of necrosis, in which the fungus thrives. The tissue response to the fungus includes pyogenic inflammation, but there is little tendency for granuloma formation. A second form of disease is pulmonary mucormycosis, in which infection occurs in the lung or, less commonly, in proximal airways. The disease resembles invasive pulmonary aspergillosis and occurs, although much less commonly, in the same substrate: patients with profound neutropenia and patients in whom phagocyte function is depressed by high-dose glucocorticoid therapy. Like *Aspergillus* species, agents of mucormycosis are angioinvasive in the lung, leading to tissue necrosis and eventually to pyemic spread to distant sites, including the skin, kidney, and brain. Rare forms of mucormycosis include a direct cutaneous infection that can complicate severe burns and contaminated wounds and the gastrointestinal form of the illness, associated with profound protein malnutrition (usually in infants), in which organisms directly invade the bowel wall, causing hemorrhage, bowel infarction, peritonitis, and death.

When uncontrolled diabetes is the main predisposing factor, rhinocerebral mucormycosis is more common. When hematologic malignancy and organ transplantation are the predisposing

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

factors, pulmonary mucormycosis is more common. Patients being treated for leukemia and bone marrow transplantation recipients appear to have an increasing risk of pulmonary mucormycosis. Early use of fluconazole for these indications reduced *Candida* infections but likely shifted what was once a reasonably even split between disseminated candidiasis and invasive aspergillosis more heavily toward aspergillosis. More recently, other triazoles, including itraconazole and now voriconazole, that are highly active against *Aspergillus* species have been used for prophylaxis, reducing *Aspergillus* infections but likely resulting in higher relative frequency of mucormycosis. There are several studies implicating itraconazole and voriconazole prophylaxis as independent risk factors for development of invasive mucormycosis.

CLINICAL MANIFESTATIONS

Rhinocerebral mucormycosis is an extremely fulminant infection. Infection begins in the nose, sometimes manifested by dark, blood-tinged discharge from one or both nostrils. Necrosis of the nasal septum and turbinates then follows, with spread to the paranasal sinuses. In sequence, the disease accelerates with ulceration and necrosis of sinus walls, periorbital cellulitis, and direct invasion of the orbit, eye, cavernous sinuses, and brain. Arterial thrombosis adds to the extent of tissue destruction. Early clinical findings include eye pain, decreased visual acuity, and cranial nerve palsies. A black eschar from ischemic necrosis, either in the nose or on the palate, is a strong signal of disease presence. Early symptoms and signs may be followed by seizures and progressive decrease in level of consciousness. Death may occur in 1 week.

Pulmonary mucormycosis is acquired by inhalation or possibly by microaspiration from colonized sinuses. The disease presents as an acute or subacute pneumonia, with fever, cough, and purulent sputum. Some patients have pleuritic pain and hemoptysis from superimposed pulmonary infarction caused by invasion of pulmonary vessels. The most characteristic finding on chest radiograph is an area of consolidation, often peripheral and sometimes wedge-shaped. Focal areas of consolidation often cavitate as the infection progresses. The spectrum of radiographic abnormalities also includes large masses (even to 6 to 10 cm in size), multiple nodules, and multiple peripheral infiltrates. The computed tomography (CT) halo sign (ground-glass changes surrounding a dense central nodule) was first reported in invasive pulmonary aspergillosis (the most common cause of this finding in immunosuppressed patients), but also occurs in mucormycosis (with similar frequency as in aspergillosis) and in other infections and conditions, including bronchoalveolar carcinoma (the most common cause in immunocompetent patients). The CT reverse halo sign (central ground-glass area surrounded by denser consolidation) seems to be relatively more common in mucormycosis (the most common cause in immunosuppressed patients) than in aspergillosis, but also occurs in other infections and conditions, including cryptogenic organizing pneumonia (the most common cause in immunocompetent patients). The CT halo signs may be helpful in individual patients, but lack great sensitivity and specificity.

Metastatic abscesses may develop in the brain, liver, spleen, kidney, and skin. Metastatic skin lesions often show extensive necrosis (ecthyma gangrenosum) and offer easy diagnosis with a simple punch biopsy. Clinically, pulmonary mucormycosis with or without pyemic dissemination cannot easily be distinguished from invasive aspergillosis. Most cases occur in patients with hematologic malignancy with prolonged neutropenia. Cases of pulmonary mucormycosis also occur in organ transplant recipients, in patients receiving prolonged courses of high-dose glucocorticoid therapy for malignant or nonmalignant disorders, and even in diabetic patients.

Deferoxamine therapy, used for chelation in some patients receiving long-term dialysis and in other iron-overloaded states, is also a risk factor for mucormycosis because it is a siderophore, mobilizing iron from peripheral storage sites and making it more available to the fungus as a growth factor.

Endobronchial mucormycosis is a rare form of pulmonary mucormycosis that has been reported mainly in patients with advanced acquired immunodeficiency syndrome (AIDS). Patients have cough, purulent sputum, and often hemoptysis. Physical findings may include a localized wheeze. The chest radiograph may be normal or may show segmental or even lobar infiltrates with significant volume loss distal to the obstructed airway. Several other unusual forms of mucormycosis have also been reported in this population. Isolated renal mucormycosis has been described in AIDS patients who abuse drugs intravenously or have long-term intravascular access catheters for various therapeutics. Nodular skin lesions

have also been reported in AIDS patients who abuse drugs intravenously. Cerebral mucormycosis of the basal ganglia has also been reported in similar patients.

Cutaneous mucormycosis can also complicate contaminated wounds via direct inoculation, rather than pyemic spread. This has been reported from war theaters including those in Afghanistan. It can also complicate civilian trauma; a total of 13 cases were reported following a tornado in Joplin, Missouri, in 2011. The causative organism in all cases was an *Apophysomyces* species. There was an association between fungal infection and penetrating wounds containing wood, soil, gravel, and other foreign material. The patients developed a cutaneous necrotizing infection within a few days of the trauma; 5 of the 13 patients died.

DIAGNOSIS

The diagnosis of rhinocerebral mucormycosis can often be strongly suspected based on the setting of diabetic ketoacidosis and the clinical features of the illness. Specific diagnosis usually depends on demonstration of characteristic broad nonseptate hyphae in biopsies of diseased tissue (Figure 174.1). Positive cultures are confirmatory and also serve to define the exact species causing the infection. PCR may play an increasing role in the future for species identification. Positive cultures for causative organisms of mucormycosis must be interpreted cautiously and in clinical context because the organisms are ubiquitous in the environment and occasionally can be recovered from the skin, pharynx, and sputum of patients without disease. No useful skin tests or serologic tests are available.

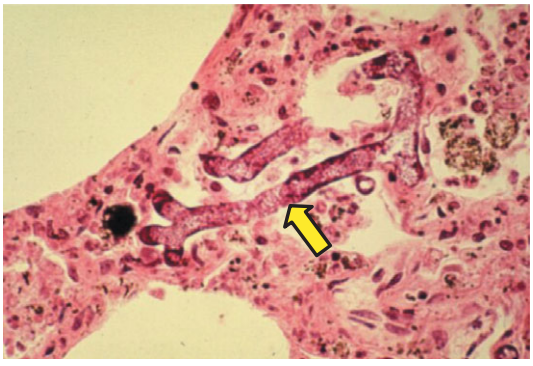

Figure 174.1 Mucormycosis: Hyphae (*arrow*) vary from 6 to 50 μm in diameter, are nonseptated, and typically branch at 90° angles. (Courtesy of www.doctorfungus.org © 2007.)

The diagnosis of pulmonary mucormycosis is also highly dependent on clinical awareness in high-risk clinical settings, with leukemia and bone marrow transplantation most important predispositions, followed by organ transplantation. Prior use of itraconazole or voriconazole for prophylaxis or empiric antifungal therapy may also be a risk factor. The disease resembles invasive aspergillosis in similar hosts and can be distinguished only by histopathology or by culture.

TREATMENT

Rhinocerebral mucormycosis has a very high mortality, beyond 50% of cases in many series. Successful therapy is most likely if the diagnosis is made early and initiation of therapy is based entirely on clinical findings, before confirmation by histopathology or culture. There are three aspects to the treatment. First, the diabetic ketoacidosis must be controlled. Second, and most importantly, aggressive surgical debridement of all necrotic tissue must be done. Sometimes several procedures are needed as the limits of the diseased tissue become more apparent. Finally, full doses of amphotericin B (AMB) must be given quickly. Use of lipid-based formulations of AMB (AMB-L) have become standard because of lower toxicity and likely superior efficacy. Usual dose of AMB-L is 5 mg/kg/day – higher dosing to 7.5 or 10 (or even higher) mg/kg/day has been used in select cases, but has higher toxicity.

Pulmonary mucormycosis is also highly lethal. Once there is spread to distant sites and particularly to the brain, fatal outcome is nearly certain. Localized pulmonary disease can sometimes be managed successfully. Again, a three-pronged approach is necessary. First, the predisposing causes must be reversed. This means return of neutrophils (either spontaneously or aided by marrow-stimulating biologicals) and/or rapid taper of glucocorticoid therapy to the extent it is possible. Second, AMB-L should be started and escalated quickly to full dosages. Third, if the patient stabilizes, strong consideration should be given to surgical resection of necrotic lung tissue, if the lung disease is localized and the risk of thoracotomy is reasonably low. There are anecdotal reports of successful treatment of pulmonary mucormycosis by surgical resection alone. In those rare cases, the preoperative diagnosis was uncertain, total excision of all involved lung was

accomplished, the diagnosis was established by histopathology of the resected tissue, and the patient recovered fully without other therapy.

When possible, isolated renal mucormycosis in patients with AIDS should be treated with nephrectomy combined with AMB-L. When nephrectomy is either not possible or is not a reasonable option given the overall condition of the patient, AMB-L alone should be used. There are some anecdotal successes using AMB-L without surgery.

Cutaneous mucormycosis is treated with aggressive surgical debridement and aggressive antifungal therapy, with AMB-L the first-line therapy.

As mentioned above, itraconazole and voriconazole are triazoles with activity against *Aspergillus* but no activity against Mucorales species. Wide use of these agents for prophylaxis and empiric antifungal therapy in patients with hematologic malignancy likely has increased the incidence of mucormycosis.

A possible advance in treatment of mucormycosis is posaconazole, the first triazole compound with activity against Mucorales species. Compassionate use in a large series of 91 patients with mucormycosis (69 proven disease, 22 probable) who had failed or were intolerant to prior antifungal treatment (usually a form of AMB) showed a success rate of 60% at 12 weeks. That exceeds historical success rates with prior standard therapy. Although posaconazole is not yet approved for use in mucormycoses, one approach pending further data might be to start patients with proven disease on AMB-L plus posaconazole until clinical response, and then extending posaconazole to 12 or more weeks. However, posaconazole is available only in oral formulation, limiting its use in critically ill patients. For now, AMB-L remains standard treatment with posaconazole used as an adjunctive, salvage, or continuation therapy on an individual case basis.

Echinocandins are another possible candidate for combination therapy. *Rhizopus oryzae* (the most common *Rhizopus* species causing infection) expresses the enzyme 1,3 β-glucan synthetase, which is the target enzyme for the echinocandins. Use of echinocandins in animal models has shown additional benefit when combined with AMB-L. There are anecdotal reports of successful use in selected cases, usually in combination with AMB-L. At present there is more experience and a larger number of positive clinical reports with posaconazole as a second agent or for salvage, and for now echinocandins should not be used as an alternate therapy versus AMB-L.

As mentioned, iron availability is an important promoter of growth for Mucorales species and deferoxamine, which mobilizes iron and also increases availability of iron to the organisms, is a risk factor for mucormycosis. However, newer iron chelators such as desferasirox bind iron but are not used as siderophores by Mucorales and thus deprive the fungus of iron availability. In models of mucormycosis in mice, desferasirox was as effective as AMB-L and it also had additive effects when used together with AMB-L. Anecdotal reports have suggested some benefit in patients, but a very small (20 patients) randomized prospective trial showed poorer outcome (more frequent death at 30 and 90 days and lower global success) when desferasirox was used in combination with AMB-L for initial therapy of mucormycosis. At present desferasirox should not be used as combination therapy with AMB-L or other agents.

Finally, hyperbaric oxygen therapy has been proposed, based on limited and anecdotal reports, as an adjunctive therapy for some patients with mucormycosis. As for other unproven therapies, hyperbaric oxygen can be considered for selected patients.

175. *Sporotrichum*

Ronald A. Greenfield

Sporotrichosis is a subacute or chronic fungal infection caused by *Sporothrix schenckii* and related species. It occurs most commonly in cutaneous or lymphocutaneous forms resulting from direct inoculation of the pathogen but also occurs in a variety of extracutaneous forms. Among the extracutaneous forms, a primary sporotrichotic pneumonia, presumably acquired by inhalation, occurs rarely. More commonly, musculoskeletal or osteoarticular sporotrichosis occurs, either as a result of direct inoculation into tendons, bursae, and joints or as a result of hematogenous dissemination. Hematogenous dissemination may result in disseminated cutaneous sporotrichosis and/or infection of a variety of unusual sites, including the meninges.

EPIDEMIOLOGY

Sporothrix schenckii is widely distributed in nature; it grows on plant debris in soil, and on the bark of trees, shrubs, and garden plants. The fungus and the disease occur in much of the world, primarily in the tropical and temperate zones. The abundance of the organism and the reported incidence of the disease show great geographic variation, perhaps related to genotypic differences between organisms in different locales. The penetrating trauma that introduces the fungal conidia into the human host is most commonly accomplished by splinters, thorns, or woody fragments of plants, but any contact with plants or plant products (e.g., sphagnum peat moss, mulch, hay, timber) accompanying minor skin trauma may initiate infection. Activities most frequently associated with acquisition of sporotrichosis include gardening (particularly rose gardening), landscaping, farming, berry-picking, horticulture, and carpentry. Skin test and serologic surveys demonstrate that most *S. schenckii* inoculations promote the development of immunity without clinically apparent infection. Zoonotic transmission also occurs from infected animals, particularly cats with extensive skin lesions, but may result from the scratch of any digging animal. Both pulmonary and disseminated sporotrichosis appear to occur more commonly in patients with a history of alcoholism.

Patients with immunosuppression due to human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) appear to more frequently develop disseminated cutaneous sporotrichosis and hematogenously disseminated sporotrichosis, including sporotrichotic meningitis, than immunocompetent hosts. Although the incidence of HIV/AIDS-associated sporotrichosis is not precisely known, it is less than that of other endemic mycoses. Patients treated with immunosuppressive agents, including tumor necrosis factor-α antagonists, have also developed disseminated sporotrichosis.

LABORATORY DIAGNOSIS

Definitive diagnosis of sporotrichosis requires the isolation of *Sporothrix* spp. in culture specimens from a normally sterile body site. Occasionally, the organism can be visualized in biopsied tissue specimens stained with periodic acid–Schiff, Gomori methenamine silver, or immunochemical stains (Figure 175.1). The organism can be recovered by fungal culture from sputum, pus, synovial fluid, bone drainage, and surgical specimens. Concentrations of organisms in joint fluid and particularly cerebrospinal fluid may be relatively low. Therefore, repetitive large-volume cultures may be required for diagnosis. Serologic techniques for measurement of antibody are available but exhibit significant interlaboratory variability in sensitivity and specificity; they are best used to suggest the need for more aggressive attempts at definitive diagnosis.

CLINICAL MANIFESTATIONS

Cutaneous sporotrichosis

The primary lesion develops at the site in the skin, 20 to 90 days after inoculation, most typically distally in the upper extremities. Over a few weeks, the initial small nodule enlarges, reddens, becomes pustular, and ulcerates, releasing purulent material from which the organism is readily cultured. Patients are typically afebrile and not systemically ill. In the lymphocutaneous form of the disease, an ascending chain of nodules develops along lymphatic channels of the skin, with the older distal lesions ulcerating and draining and the younger, more proximal lesions forming subcutaneous nodules that attach to the skin as they age and begin to ulcerate (Figure 175.2). The lesions are usually minimally painful, but extensive disease may result in functional impairment. Some patients exhibit no lymphangitic spread, and the disease presents as an indolent ulcerating plaque that persists for years if untreated (fixed cutaneous sporotrichosis). Patients often have received courses of antibacterial therapy without benefit before the process is recognized as sporotrichosis. The lymphocutaneous form of sporotrichosis can be mimicked by infection with *Nocardia*, *Mycobacterium marinum* and other mycobacteria other than tuberculosis, *Leishmania*, and *Francisella tularensis*.

Pulmonary sporotrichosis

Pulmonary sporotrichosis is a subacute or chronic pneumonitis with cavitation, usually in the upper lobes, clinically indistinguishable from mycobacterial infection or chronic pulmonary histoplasmosis. Almost all patients have underlying chronic obstructive pulmonary disease. They present with productive cough, sometimes with weight loss and increasing dyspnea, but rarely with fever, chills, or sweats. Diagnosis requires isolation of *S. schenckii* from sputum cultures or its histopathologic recognition in biopsy specimens.

Osteoarticular sporotrichosis

Lesions of deeper tissues may occur in almost any organ, but there is a distinct predilection for the joints, particularly of the extremities, and the long bones adjacent to these joints. The resulting chronic arthritis is often confused with rheumatoid or other chronic inflammatory arthritis, not infrequently for 10 or more years, until destruction of adjacent bone or development of draining fistulas encourage efforts to establish the microbial etiology of the chronic osteomyelitis. Cutaneous or lymphocutaneous lesions are unusual in these patients. The process generally begins in a single joint, but additional joints may be involved successively. The patient usually has pain on motion, and the involved areas may be warm and red. Functional impairment resulting from osteoarticular sporotrichosis can become very severe.

Disseminated sporotrichosis

Sporotrichotic lesions occur infrequently in many other organs such as the eye, the prostate, the oral mucosa, and the larynx, and the clinical manifestations in these patients depend on the organ

Table 175.1 Treatment of sporotrichosis

Form of sporotrichosis	Preferred treatment	Alternative agents
Cutaneous or lymphocutaneous	SSKI, itraconazole, terbinafine	Fluconazole, posaconazole, amphotericin B
Pulmonary	Itraconazole	Amphotericin B
Osteoarticular or musculoskeletal	Itraconazole	Amphotericin B
Disseminated	Amphotericin B	Amphotericin B plus flucytosine, itraconazole step-down therapy

Abbreviation: SSKI = saturated solution of potassium iodide.

involved. Involvement of the central nervous system (CNS) and meninges, which was distinctly rare in the pre-AIDS era, has become more common but is still rare in persons living with AIDS. Patients may present with subtle changes in mental status as the only symptom and are found to have chronic lymphocytic meningitis. Recovery of the fungus from extracutaneous lesions may be difficult, particularly in meningitis.

THERAPY

Spontaneous healing of the cutaneous forms of sporotrichosis has been reported, but without treatment, the lesions usually progress slowly with draining and scarring. In immunocompetent patients, the infection is not life threatening. Treatment options are presented in Table 175.1. Historically, cutaneous and lymphocutaneous sporotrichosis have been treated with saturated solution of potassium iodide (SSKI), although the mechanism of action has not been determined. An initial dose of 5 to 10 drops diluted in liquid, preferably fruit juice, is given three times daily after meals, and increased dropwise to 120 drops per day or the maximum tolerated by the individual patient (frequently <60 drops per day). Although relatively inexpensive, this form of therapy is poorly accepted by many patients due to adverse effects, including increased lacrimation, increased salivation, metallic taste perversion, salivary gland swelling, gastrointestinal upset, and frequent rash.

Itraconazole is the treatment of choice for lymphocutaneous sporotrichosis; 100 mg orally daily for 3 to 12 months, determined by continuing treatment for 2 to 4 weeks beyond resolution of all lesions. Itraconazole can be given either as capsules that must be taken with food and must not be coadministered with therapies that suppress gastric acidity and that have somewhat erratic absorption or as an itraconazole oral solution, which is less palatable and generally more expensive but avoids these drawbacks. In patients who do not respond to itraconazole initially, one can consider increasing the dosage of itraconazole to 400 mg/day. Therapy with terbinafine, 250 mg orally daily, appears to be as effective as itraconazole therapy. By historical comparison, treatment with fluconazole, 200 to 400 mg orally daily, was less effective than itraconazole. The effectiveness of higher doses of fluconazole is subject to speculation. Amphotericin B preparations should only be necessary as a treatment of last resort for patients with cutaneous or lymphocutaneous sporotrichosis. Because many strains of *S. schenckii* that cause fixed cutaneous sporotrichosis grow poorly in the laboratory at 37°C, local application of heat may be an effective adjunct to antifungal therapy.

Pulmonary sporotrichosis should be treated with either itraconazole, 200 mg orally twice daily, for patients with non-life-threatening infection or with an amphotericin B preparation (preferably a liposomal amphotericin B preparation because of better tolerability) in patients with life-threatening or extensive pulmonary infection. For the latter patients who have the lung capacity to tolerate such a procedure, treatment with an amphotericin B preparation with subsequent surgical resection of involved lung areas may be the best therapy.

Itraconazole, 200 mg orally twice daily, should be initial therapy for patients with osteoarticular sporotrichosis. As with other joint and bone infections, drainage and debridement may be important surgical adjuncts to antimicrobial therapy. Conventional amphotericin B therapy appears to be approximately as effective as itraconazole but is less convenient and associated generally with more frequent adverse reactions; therefore, it is generally used only after failed itraconazole therapy. The role of liposomal amphotericin B preparations in osteoarticular sporotrichosis has not been defined. Fluconazole has been used with only modest success in osteoarticular sporotrichosis. Itraconazole treatment should generally be continued for

12 months, therapy with amphotericin B preparations for 6 to 10 weeks. Voriconazole has poor activity in vitro against sporotrichosis and should not be used. Posaconazole has in vitro activity, but its role in vivo is undefined.

Sporotrichotic meningitis should be treated with amphotericin B, based on limited numbers of anecdotally reported cases; liposomal amphotericin B is preferred because of increased penetration into the cerebrospinal fluid. Based on possible in vitro synergy and anecdotal reports, the addition of flucytosine may be beneficial for patients with recalcitrant meningitis. Itraconazole may offer effective step-down therapy after clinical improvement.

An amphotericin B preparation should be considered initial therapy for patients with disseminated sporotrichosis with or without AIDS. Itraconazole might be used for non-life-threatening infection and in cases in which meningitis has been actively excluded. Itraconazole may also play a role in lifelong suppressive therapy for patients with disseminated sporotrichosis and AIDS after initial induction therapy with an amphotericin B preparation.

176. *Cryptococcus*

William G. Powderly

Cryptococcus neoformans, which is found worldwide as a soil organism and thought to be transmitted by inhalation, most often causes disease in patients with abnormal cell-mediated immunity, notably patients with human immunodeficiency virus (HIV) infection and solid organ transplant recipients, but the infection also occurs rarely in apparently immunocompetent persons. It is the most common systemic fungal infection in patients infected with HIV. It is estimated that over 1 million cases of invasive cryptococcal infection occur annually in patients with acquired immunodeficiency syndrome (AIDS) worldwide with more than 600 000 deaths each year. Most of these cases occur in resource-poor settings, especially in sub-Saharan Africa. With the advent of effective antiretroviral therapy (ART), cryptococcal infections have become much less common in the United States.

Two varieties of *C. neoformans* exist, distinguishable by serology: *C. neoformans var. neoformans* (serotypes A and D) and *C. neoformans var. gattii* (serotypes B and C). Virtually all HIV-associated infection is caused by *C. neoformans var. neoformans*. *C. neoformans var. gattii* is endemic in Australia and recent outbreaks of *C. neoformans var. gattii* infection have occurred in the Pacific northwestern parts of North America.

PRESENTATION AND DIAGNOSIS

The most common manifestation of cryptococcal infection is meningitis. Most patients develop insidious features of a subacute meningitis or meningoencephalitis, with fever, malaise, and headache, and are generally symptomatic for at least 2 to 4 weeks before presentation. In patients with a more subacute or chronic course, mental status changes such as forgetfulness and coma can also be seen. Classic meningeal symptoms and signs such as stiff neck and photophobia occur in only about one-quarter to one-third of all patients and generally are less likely to occur in HIV-positive patients. The typical pattern in the cerebrospinal fluid (CSF) is chronic meningitis with a lymphocytic pleocytosis. However, the CSF may appear normal in HIV-positive patients with cryptococcal meningitis because the usual response to infection is usually markedly blunted. In fact, fewer than half of HIV-positive patients with cryptococcal meningitis have an elevated protein level, only about one-third have hypoglycorrhachia, and only about 20% have more than 20 white blood cells per cubic millimeter of CSF. The opening pressure is usually elevated in patients with cryptococcal meningitis (up to 70% of patients present with pressures greater than 20 cm H_2O) and is an important issue associated with therapy. India ink stain of the CSF is positive, showing encapsulated yeast, in about 75% of cases and the cryptococcal antigen titer in the CSF is almost invariably positive with sensitivity of 93% to 100% and specificity of 93% to 98%. Serum cryptococcal antigen (sCRAG) is elevated in 95% of patients with meningitis. A positive sCRAG with titer above 1:8 suggests disseminated cryptococcosis. Such patients should be evaluated for possible meningeal involvement. False-positive sCRAG can happen secondary to infection with *Trichosporon beigelii* and secondary to residual disinfectant on laboratory test slides. Culture of *C. neoformans* from any body site should also be regarded as an indication for further evaluation and initiation of therapy. However, colonization of *Cryptococcus* can be found in the respiratory system. Patients with isolated positive respiratory cultures for *C. neoformans* should be carefully evaluated for disseminated infection; therapy might not be necessary in immunocompetent patients with no symptoms and negative sCRAG.

Cryptococcus neoformans can invade sites other than the meninges. Isolated pulmonary disease has been well described. It usually presents as a solitary nodule in the absence of other symptoms. Cryptococcus pneumonia has also been described. In immunocompromised patients, especially

Table 176.1 Drugs used in the treatment of cryptococcal infection

Drugs	Dosage	Side effects	Drug interactions	Comments
Amphotericin B	0.7–1.0 mg/kg/d 3–6 mg/kg/d (liposomal) 5 mg/kg/d (lipid complex)	Immediate hypersensitivity reaction, fever, hypotension, nausea and vomiting during administration, hypokalemia, and nephrotoxicity	Nephrotoxic drugs (e.g., aminoglycosides, pentamidine, foscarnet, cidofovir)	Liposomal or lipid complex formulation should be considered in patients with renal dysfunction
Flucytosine (5-FC)	25 mg/kg q6h	Gastrointestinal, bone marrow suppression	Nephrotoxic drugs	Dosage must be reduced in patients with renal dysfunction; drug level should be monitored
Fluconazole	400 mg/d (acute therapy), 200 mg/d (suppressive therapy)	Nausea, rash, and hepatitis	Rifabutin (increased rifabutin levels); rifampin (decreased fluconazole levels)	Dosage may need to be adjusted in renal dysfunction
Itraconazole	200–400 mg BID	Nausea, abdominal pain, rash, headache, edema, and hypokalemia	Rifamycins, ritonavir, phenobarbitol, phenytoin all decrease itraconazole levels The effect of nevirapine is unknown; the drug should not be used concomitantly with terfenadine or astemizole Antacids, histamine blockers decrease itraconazole absorption Itraconazole itself acts as a moderate inhibitor of cytochrome P450 system and can increase levels of indinavir, cyclosporin, digoxin, and phenytoin	Absorption of itraconazole is dependent on food and gastric acid and may be erratic; the newer solution is better absorbed

those with AIDS, disseminated disease is common. About half of HIV-positive patients with cryptococcal meningitis have evidence of pulmonary involvement at presentation, with clinical symptoms such as cough or dyspnea and abnormal chest radiographs. The chest radiographic finding is usually diffuse interstitial infiltrates in immunocompromised patients or focal lesions in immunocompetent patients. Concomitant opportunistic infections, especially with *Pneumocystis jirovecii* (*carinii*), occur in about 15% to 35% of patients. Cutaneous involvement is common and with this presentation suggests disseminated disease. The most common skin involvement resembles that of molluscum contagiosum. As many as three-quarters of patients with cryptococcal meningitis have positive blood cultures. Infection of bone, eye, adrenal glands, prostate, and urinary tract has also been described. The prostate gland represents a reservoir of infection and potential source of reinfection after completion of therapy.

THERAPY

Management of cryptococcal infection depends on the extent of disease and the patient's immune status. A solitary pulmonary nodule in a normal host may not need treatment, provided the patient has careful follow-up. The advent of relatively safe antifungals such as fluconazole permits a short course of therapy for most patients with localized disease. Extrapulmonary disease is generally managed in the same way as meningitis. A search for potential underlying problems should be initiated in patients who are not known to be immunosuppressed, including an HIV antibody test and CD4 lymphocyte count, because cryptococcal infections have been described as one of the manifestations of so-called isolated CD4 T-cell lymphocytopenia. Drugs generally used in the treatment of cryptococcal infection are summarized in Table 176.1.

Cryptococcal infection in normal hosts

Untreated cryptococcal meningitis is uniformly fatal, so all patients with meningitis must be treated. Most of the available evidence suggests that amphotericin B-based therapy remains the gold standard and the combination of an amphotericin B preparation plus flucytosine (5-FC) should be regarded as the best initial treatment. Recent studies indicate that this combination is most likely to lead to more effective and more

Table 176.2 Factors predicting relapse of cryptococcal meningitis

Immunosuppression
Presentation with neurologic abnormalities
CSF leukocyte count $\leq$20 cells/mm^3
CSF antigen titer >1:32
Positive India ink stain after 4 wk of treatment
CSF antigen titer greater than 1:8 after 4 wk of treatment

Abbreviation: CSF = cerebrospinal fluid.

rapid clearance of the fungus from the CSF, which is probably the best surrogate marker for ultimate successful therapy. This conceptual approach is consistent with clinical trial data in AIDS that amphotericin B-based therapy is superior to initial therapy with azoles. The different amphotericin B preparations have not been shown to have important differences in response rates of cryptococcal meningitis, although clearly the lipid-based formulations are less toxic than amphotericin B deoxycholate. Because some degree of nephrotoxicity is inevitable if amphotericin B deoxycholate is given for 4 to 6 weeks, current recommendations suggest that liposomal amphotericin at a dose of 5 mg/kg is the preferred treatment for cryptococcal meningitis in normal hosts. Although it is unclear whether 5-FC is necessary in normal hosts, extrapolation from trials in patients with AIDS would suggest that it accelerates clearance of the fungus and improves mortality. The recommended dosage is 37.5 mg/kg four times daily. Levels must be measured to minimize toxicity (especially bone marrow suppression), and dosages must be adjusted for renal insufficiency.

The duration of therapy is not well defined for patients with cryptococcal infection. Normal subjects with no evident risk factors for a poor outcome respond well to 4 weeks of combination therapy, and this is often curative. Prolonged therapy should be considered for patients at risk of relapse (Table 176.2). Pulmonary cryptococcosis without meningeal involvement can be treated initially with fluconazole. However, for meningitis, there is no controlled trial of fluconazole, especially comparing initial azole therapy with an amphotericin B-based regimen. With current data, amphotericin B plus 5-FC is still recommended as standard therapy for cryptococcal meningitis. Fluconazole can be used to treat patients (or to complete a course of treatment in patients) who cannot tolerate amphotericin B or patients without neurological involvement. In many circumstances (need for intravenous access, difficulties with outpatient parenteral therapy, toxicity) a full course of parenteral amphotericin B is impractical or undesirable, and a switch to fluconazole is preferred. Timing of such a switch is uncertain. There is insufficient evidence to advocate using changes in cryptococcal antigen as a guide to making treatment decisions, but it is probably reasonable to consider using the clearance of yeast from CSF as an indicator for switching treatment from polyene to oral azole therapy. In most patients, this is likely to take 2 to 3 weeks to achieve, suggesting this is probably the minimum amount of amphotericin B therapy that should be used.

Once patients have been switched to fluconazole, the next question becomes how long to treat? Unfortunately, there are absolutely no well-controlled studies to answer this question. Given the potential severity of cryptococcal infection, the most prudent recommendation would be to treat with fluconazole for 6 to 12 months after clearance of CSF has been documented.

Cryptococcal infection in AIDS

In patients with AIDS, the acute mortality with cryptococcal meningitis ranges from 10% to 25%. Multiple clinical factors have been identified in studies as predictors of a poor outcome, as summarized in Table 176.3. The current recommendations for the treatment of cryptococcal meningitis in AIDS are to use a combination of amphotericin B (either deoxycholate or a liposomal preparation) plus 5-FC (25 mg/kg every 6 hours) for at least 2 weeks followed by at least 8 weeks of fluconazole, 400 mg PO daily. This strategy was first evaluated in a large randomized trial conducted by the National Institutes of Allergy and Infectious Diseases Mycosis Study Group (MSG) and AIDS Clinical Trials Group (ACTG). Patients with cryptococcal meningitis were randomized to receive 2 weeks of amphotericin B (0.7 mg/kg/day) with either 5-FC (25 mg/kg every 6 hours) or matching placebo. The study was designed to address two questions: (1) Does adding 5-FC to amphotericin B as induction therapy for cryptococcal meningitis improve 2- or 10-week survival compared with induction with amphotericin B alone and (2) is itraconazole as effective as fluconazole in suppressing relapse of cryptococcal meningitis during the maintenance phase of treatment? At the end of 2 weeks, patients who were stable or improved were again randomized to receive either fluconazole, 400 mg/day, or

Table 176.3 Factors at baseline predictive of a poor outcome in AIDS patients with cryptococcal meningitis

itraconazole, 200 mg twice daily. The acute mortality with this regimen was 6%. The addition of 5-FC to amphotericin B did not improve the mortality and clinical course. However, 5-FC was well tolerated. Furthermore, the use of 5-FC as initial therapy has been associated with a decreased risk of later relapse of cryptococcal meningitis. There was no significant difference in clinical symptoms, response rate, or mortality among patients randomized to either fluconazole or itraconazole. This approach has recently been validated by a large randomized trial comparing amphotericin B plus 5-FC to amphotericin B plus fluconazole and to amphotericin B alone. There were fewer deaths among patients receiving amphotericin B and 5-FC compared with those receiving amphotericin B alone, whereas combination therapy with fluconazole had no significant effect on survival, as compared with amphotericin B alone.

There have been a number of controlled comparative trials of the orally active antifungal triazoles, fluconazole and itraconazole. In each trial, the azole antifungals were effective in about 50% of patients. Similarly, in a study directly comparing fluconazole and itraconazole, fewer than 50% of patients responded to either drug. Thus at least 50% of patients treated initially with azole antifungals will fail to respond. Most studies of amphotericin B report response rates of 70% to 80% or more.

The availability of the alternative formulations of amphotericin B raises the issue of their use in cryptococcal meningitis. Several studies have shown that both liposomal amphotericin B and amphotericin B lipid complex are effective in AIDS-associated cryptococcal meningitis. None show superiority to amphotericin B deoxycholate, and most patients tolerate a short course of amphotericin B deoxycholate (10–14 days) without significant nephrotoxicity. Thus the role of lipid preparations of amphotericin B in AIDS-associated cryptococcal meningitis remains uncertain, although they may be useful in patients with impaired renal function. There have been some studies looking at high doses of fluconazole and at fluconazole–5-FC combinations, but none are robust enough to allow any recommendations. Voriconazole and posiconazole are active against *C. neoformans*, but clinical experience is limited.

An important aspect of management of acute cryptococcal meningitis in AIDS is the recognition that clinical deterioration may be caused by increased intracranial pressure (ICP), which may not respond rapidly to antifungal therapy. Analyses have shown a relationship between baseline opening pressure and long-term outcome, with the median survival in patients with the highest pressures being significantly less than that in patients whose pressures were normal. I believe that all patients with cryptococcal meningitis should have opening pressure measured when a lumbar puncture is performed, and strong consideration should be given to reducing such pressure if the opening pressure is high (>25 cm H_2O). Lumbar puncture with removal of 30 mL of spinal fluid daily is often effective. If elevated opening pressure persists with neurologic symptoms despite serial lumbar puncture, lumbar drainage should be considered. Some patients have required placement of lumbar peritoneal shunts for persistently elevated ICP despite successful antifungal therapy. Neither acetazolamide nor corticosteroids are effective in this situation, and may be detrimental, so they should not be used.

The advent of effective ART has changed the natural history of AIDS-related cryptococcal infection. Prior to effective HIV therapy, lifelong maintenance therapy was required in AIDS patients with cryptococcal infection to prevent relapse of infection. Relapse rates of 50% to 60% and a shorter life expectancy were reported in patients who did not receive long-term suppressive therapy. Fluconazole, 200 mg daily, is the drug of choice. Routine monitoring by measurement of sCRAG has not been shown to predict relapse, although elevations of antigen in the CSF may predict recurrence. However, it is now clear that long-term suppressive treatment can be stopped after at least 12 months of antifungal therapy if the patient's immune system recovers with ART (usually defined as the CD4+ T-cell count increasing to >200 cells/mm^3).

All HIV-positive patients with cryptococcal meningitis should receive ART. Recent studies

evaluating the timing of ART in AIDS patients with cryptococcal meningitis suggest a higher mortality if given during the acute treatment for cryptococcal infection. Consequently ART initiation should be deferred for 6 to 8 weeks after initiation of antifungal therapy. Efavirenz-based therapy has been shown to be well tolerated in patients receiving fluconazole for cryptococcal meningitis.

It is thought that a likely mechanism for increased mortality with early initiation of ART is immune reconstitution inflammatory syndrome (IRIS), which is a more vigorous inflammatory response to the underlying infection associated with restoration of the immune system. The pathogenesis of IRIS is unclear but is thought to represent an overexuberant immunologic response to a high antigen load in the context of an immune response that is recovering but not yet fully normal. Clinically there can be considerable morbidity and even mortality. In the case of cryptococcal meningitis, IRIS may manifest as an apparent recurrence of meningitis, with all the features of the initial meningitis presentation. Lumbar puncture will typically show inflammation but, by definition, will remain culture negative. Rarely, the syndrome may present outside the central nervous system (CNS) as pulmonary infiltrates or hilar/mediastinal lymphadenitis due to extra-CNS *Cryptococcus*. Typically IRIS presents following an initial clinical improvement. The majority of cases of IRIS occur within 30 days of starting ART, and the frequency of IRIS following initiation of ART in cryptococcal meningitis has varied from 10% to 50% in different series. IRIS has been found more frequently in patients who are antiretroviral naïve before ART. It is also more commonly seen in those with a higher CSF cryptococcal antigen, probably due to increased antigen producing a greater inflammatory response. Starting ART within 30 days of diagnosis of cryptococcal meningitis is also associated with a higher likelihood of IRIS, presumably due to a greater antigenic burden. If an immune reconstitution syndrome develops in a patient receiving ART, the patient should remain on antiviral therapy and continue antifungal treatment. Anti-inflammatory treatment may be needed for symptom management, and in some cases, immunosuppressive therapy such as corticosteroids has been used.

Fluconazole, 200 mg PO daily, has been shown to be effective as primary prophylaxis in patients with advanced HIV disease. However, this has not been regarded as cost-effective in developed countries such as the United States. However, a strategy of primary prophylaxis may be appropriate in patients with advanced HIV disease (CD4+ T-cell count <100 cells/mm^3) in resource-poor settings; alternatively, screening patients using cryptococcal antigen testing and treating asymptomatic patients with positive serum antigen tests may also be effective.

Cryptococcal infection in other immunocompromised hosts

Management of cryptococcal meningitis in the setting of organ transplantation or lymphoma is also uncertain. The MSG found patients with underlying immunosuppression to have poor outcomes when treated with amphotericin B and 5-FC and to be likely to relapse. Furthermore, amphotericin B nephrotoxicity complicates the use of immunosuppressives such as cyclosporine in such patients. However, there is very little published experience with the use of fluconazole, itraconazole, voriconazole, or fluconazole plus 5-FC in this setting, and these agents are also associated with significant drug interactions. An approach similar to that used with AIDS patients (i.e., an initial period of treatment with amphotericin B plus 5-FC followed by fluconazole) is recommended. Because nephrotoxicity is an issue in many of these patients, liposomal amphotericin B is generally preferred, again for at least 2 to 3 weeks. An area of considerable uncertainty is the duration of fluconazole therapy after acute therapy. Suppressive antifungal therapy for at least 1 year after the completion of acute treatment is recommended. In some patients with persistent immunosuppression, such as solid organ transplant recipients, it may be necessary to continue treatment even further, although again there are very limited data on which to base a recommendation.

177. Histoplasmosis

Mitchell Goldman and Alvaro Lapitz

INTRODUCTION

Histoplasma capsulatum is a thermal dimorphic fungus found most frequently in soil in the midwestern United States. Bird and bat excreta rich in organic nitrogen support the growth of the fungus. Sites associated with blackbird roosts are the most common sources of outbreaks currently, whereas domestic chicken coops were a common source in the past. Recent outbreaks have occurred after cleaning a campsite contaminated by bat excreta, rototilling soil in a schoolyard below a bird roost, and digging for buried treasure. When sites are disturbed the spores become airborne, producing an infective aerosol. The lung is the portal of entry in almost every case of histoplasmosis. Spores of *H. capsulatum* are inhaled, and in the alveoli they convert to a yeast, the tissue-invasive form. The now multiplying yeasts are phagocytosed by alveolar macrophages that are initially incapable of killing the fungus. Ingested yeasts multiply inside macrophages and spread throughout the body via the lymphatics during the preimmune phase of the illness to organs rich in reticuloendothelial cells. Once adequate cell-mediated immunity (CMI) develops, the now "armed" macrophages can either kill or wall off the infecting organisms. Following a strong immune response, as is seen in immunocompetent individuals, necrosis occurs, which in time becomes calcified. These calcified granulomas are seen in the lung, hilar lymph nodes, liver, and spleen of individuals who successfully limited the infection.

Most individuals infected with *H. capsulatum* develop adequate CMI. If CMI fails to develop, progressive dissemination will occur.

CLINICAL MANIFESTATIONS

Localized pulmonary and self-limited infections

Most *H. capsulatum* infections are asymptomatic. After low-level exposure, some patients develop a localized form of infection with fever, chills, headaches, myalgia, anorexia, cough, and chest pain. Erythema multiforme or erythema nodosum may develop. The incubation time following low-level, outdoor exposure is approximately 14 days. This form of acute localized pulmonary infection is self-limited; after 2 to 4 weeks, most immunocompetent patients will have recovered completely, and treatment is usually not necessary. Chest radiographs usually demonstrate localized pneumonitis but may be normal. Ipsilateral hilar lymph nodes are usually enlarged. Healing may be complete with normalization of the radiograph but frequently multiple cycles of central necrosis and peripheral calcification occur, leaving the characteristic "coin" lesion as a proof of prior infection.

When the infective aerosol is unusually large, fulminant infection may occur, with severe hypoxemia and respiratory failure, requiring prompt and aggressive treatment. Patients who inhale large inocula may develop multiple nodular lesions of variable size. The radiologic appearance of an overwhelming infective dose is diffuse micronodular infiltrates.

Patients with emphysema may develop upper lobe infiltrates after exposure. The resultant infection may result in cavitation. The radiographic appearance of this infection mimics reactivation tuberculosis. Low-grade fever and anorexia with weight loss are common. Without treatment, most of these patients develop progressive destructive disease. The clinical and radiologic similarities to tuberculosis make the diagnosis challenging.

Late complications of healed and calcified histoplasmosis are related to the location of the calcified lymph nodes, which may involve and compress various mediastinal structures. A rare late complication is the development of mediastinal fibrosis, which can lead to crippling complications, such as the superior vena cava syndrome.

Progressive disseminated histoplasmosis

During the preimmune phase of the infection the fungus disseminates widely. With the development of adequate CMI, the cells of the reticuloendothelium are responsible for limiting spread of the disease.

In the immunosuppressed patient or at extremes of age this dissemination becomes progressive. This form of the disease is known as progressive disseminated histoplasmosis (PDH), and prognosis is poor without treatment. Fever and weight loss are the most common symptoms, and hepatosplenomegaly is frequent.

Dissemination to the oropharyngeal or gastrointestinal mucosa, skin, and adrenal glands may occur. Patients may develop respiratory distress and hepatic or renal failure, and coagulopathy and shock may complicate severe cases. Central nervous system (CNS) involvement may occur either as chronic meningitis or focal lesions. In PDH the mortality is close to 100% without treatment. In severely ill patients, mortality may still be high despite treatment.

Prior to the widespread use of cytotoxic agents and glucocorticoids, most patients with PDH had underlying lymphoreticular malignancies, most commonly Hodgkin's disease. Currently, the most common underlying disease of patients with PDH is the acquired immunodeficiency syndrome (AIDS). Through the growing use of organ transplantation and newer immune-modulating treatments such as the tumor necrosis factor (TNF) blocking agents, an increasing number of individuals remain at risk for PDH (Figure 177.1).

DIAGNOSIS

The gold standard is the recovery of the organism, but this is time-consuming, requiring up to 30 days for identification of the organism.

Sputum cultures are not very useful in the cases of suspected acute pulmonary infection because the inoculum is not high enough and only rarely do patients have productive cough. In patients with acute disseminated histoplasmosis and in those with chronic pulmonary or cavitary infections, sputum cultures are frequently positive. When bronchoscopy and bronchoalveolar lavage are employed with appropriate stains, the sensitivity of respiratory secretions increases. Biopsy of accessible lesions (Figure 177.2) and bone marrow can be used in cases of disseminated infection.

Detection of histoplasma polysaccharide antigen in urine or serum offers high sensitivity and rapid diagnosis for patients with large inoculum acute pulmonary disease and those with PDH. Sensitivity for antigen detection is higher in disseminated infections than isolated pulmonary disease. The highest sensitivity of histoplasma antigen testing is in patients with AIDS and PDH when compared to other immunosuppressed or immunocompetent individuals with PDH. Earlier generation tests were characterized by a significantly higher sensitivity of the urine test when compared to serum testing. This does not appear to be the case with the newest generation of testing. As the levels of antigen are highest in the urine for most patients, urine testing is a helpful initial strategy. Antigenemia testing may be particularly useful in anuric

patients. Antigenuria levels have correlated with disease severity and have been useful when monitoring treatment, since the levels decrease with successful therapy and increase with relapse.

Serologic complement fixation and immunodiffusion are also helpful in some cases and may be the only means by which an infection can be diagnosed in immunocompetent individuals. In immunocompetent patients, it frequently takes 2 to 6 weeks for the development of detectable antibodies. The use of antibodies for diagnosis of histoplasmosis is most helpful in chronic pulmonary histoplasmosis and for those with persistent symptoms following recent infection.

As in the case of antigen detection there is also clinical correlation between the severity of the disease and the antibody response. In immunosuppressed patients antibody responses may be weaker and in some cases undetectable.

TREATMENT

The vast majorities of patients with acute histoplasmosis are asymptomatic or have a mild self-limited disease and do not require antifungal treatment. In the few patients where treatment is required, therapy (Table 177.1) depends on the clinical scenario.

Acute localized pulmonary infection resolves without therapy in the majority of cases, and treatment is indicated only when symptoms persist for more than 4 weeks. In these patients oral itraconazole, 200 mg three times daily for 3 days, followed by oral itraconazole, 200 to 400 mg daily for 6 to 12 weeks, is recommended. In more severe cases of acute diffuse pulmonary histoplasmosis in the immunocompetent host that require hospitalization, lipid formulations of amphotericin B in doses of 3 to 5 mg/kg/day are recommended for up to 2 weeks, followed by oral itraconazole, 200 mg three times daily for 3 days, followed by oral itraconazole, 200 mg twice daily for an additional 12 weeks. The parent compound, amphotericin B deoxycholate, is also effective, but the potential for nephrotoxicity limits its use. The usual dose is 0.7 mg/kg infused daily. Methylprednisolone, 0.5 to 1.0 mg/kg/day intravenously, may be used in severely ill, hypoxemic, or ventilated patients for up to 2 weeks.

The treatment of chronic pulmonary histoplasmosis is oral itraconazole, 200 mg three times daily for 3 days, followed by 200 to 400 mg daily for at least a year. Therapy may be extended if resolution is slow. Itraconazole levels should be monitored, especially in patients where the resolution is slow. Amphotericin B is also effective when used for 12 to 16 weeks. Relapses after apparently successful treatment may occur, and close follow-up is indicated.

The treatment of severe PDH is liposomal amphotericin B at the dose of 3 mg/kg/day for 1 to 2 weeks or until clear-cut clinical improvement occurs. This is followed by oral itraconazole, 200 mg three times daily for 3 days, followed by oral itraconazole, 200 mg twice daily for at least 12 months. Other lipid preparations may be substituted in appropriate doses. Amphotericin B deoxycholate is also effective in patients at

Table 177.1 Recommendations for treatment of patients with histoplasmosis

Manifestation	Treatment
Acute pulmonary: moderately severe or severe when symptoms persist for 4 weeks or longer	Itraconazole, 200 mg 3× daily for 3 d, followed by itraconazole, 200–400 mg daily for 6–12 wk
Acute pulmonary with severe manifestations	Liposomal amphotericin, 3–5 mg/kg/d for up to 2 wk, followed by itraconazole, 200 mg 3× daily for 3 d, then itraconazole, 200 mg 2× daily for 12 additional wk Amphotericin deoxycholate, 0.7 mg/kg/d, is also effective and may be substituted for liposomal amphotericin in patient at low risk for renal damage
Chronic cavitary pulmonary	Itraconazole, 200 mg 3× daily for 3 d, followed by itraconazole, 200 mg 2× daily for at least a year. Itraconazole levels should be measured in patients where resolution is slow Amphotericin B deoxycholate may also be used at the dose of 0.7 mg/kg/d for 12–16 wk
Progressive disseminated: moderately severe/severe, with or without HIV/AIDS	Liposomal amphotericin B, 3 mg/kg/d for 1–2 wk or until stability, followed by itraconazole, 200 mg 3× daily and then 200 mg 2× daily for at least 1 yr; other lipid formulations may be used as well as the deoxycholate preparation if needed
Progressive disseminated mild to moderate	Oral itraconazole, 200 mg daily for 3 d followed by 200 mg 2× daily for at least 1 yr
Central nervous system	Liposomal amphotericin B, 5 mg/kg/d for a total of 175 mg/kg, followed by itraconazole, 200 mg 2–3× daily for at least 1 yr

low risk for renal failure. Mildly ill patients with PDH may be treated with itraconazole alone for at least 12 months. PDH in AIDS patients is treated in a similar fashion. Chronic suppressive therapy with itraconazole is recommended for patients who do not recover immune function. CNS histoplasmosis is treated with liposomal amphotericin B, 5 mg/kg/day, for a total of 175 mg/kg over 4 to 6 weeks, followed by oral itraconazole, 200 mg two to three times daily for at least 1 year.

In areas endemic for histoplasmosis, particularly when high rates of histoplasmosis are observed, prophylaxis with oral itraconazole, 200 mg daily may be considered for patients with AIDS if the CD4 count is <150 cells/mm^3.

178. Blastomycosis

Peter G. Pappas

Blastomycosis is a systemic pyogranulomatous disease caused by the thermally dimorphic fungus *Blastomyces dermatitidis*. The disease is endemic to parts of the midwestern and south-central United States and Canada, although blastomycosis has been reported worldwide, including isolated reports from Africa, Asia, and Central and South America. Within the United States and Canada, the disease is concentrated in areas along the Mississippi and Ohio River basins and the Great Lakes. In endemic areas, small point-source outbreaks of blastomycosis have been associated with recreational and occupational activities occurring in wooded areas along waterways. Current evidence indicates that *B. dermatitidis* exists in warm moist soil enriched by organic debris, including decaying vegetation and wood.

Most infections with *B. dermatitidis* occur through inhalation of aerosolized spores, although infection through direct inoculation has been reported rarely. Primary infections are usually asymptomatic or may result in a self-limited flu-like illness. Hematogenous dissemination of organisms from the lung can result in extrapulmonary manifestations.

Blastomycosis is usually recognized as a chronic, indolent systemic fungal infection associated with various pulmonary and extrapulmonary manifestations. Pulmonary blastomycosis usually manifests as a chronic pneumonia syndrome characterized by productive cough, chest pain, hemoptysis, weight loss, and low-grade fever. There are no distinguishing radiologic features of pulmonary blastomycosis, although nodular and mass lesions, with or without cavitation, often mimicking other granulomatous diseases or bronchogenic carcinoma are common. Hilar adenopathy and pleural effusions are uncommon. Rarely, diffuse interstitial infiltrates consistent with adult respiratory distress syndrome can occur secondary to blastomycosis.

Clinical manifestations of blastomycosis are highly variable. The lungs are involved in up to 90% of cases, and the skin is involved in 40% to 60% of cases. Multiple organ involvement is common, occurring in approximately 50% to 60% of cases. Osteoarticular disease is the next most common manifestation, followed by male genitourinary tract (especially the prostate and epididymis) involvement. Central nervous system (CNS) involvement occurs in fewer than 5% of patients, and can present as either granulomatous meningitis or an intracerebral mass lesion. *Blastomyces dermatitidis* is an uncommon opportunistic pathogen, but may cause overwhelming disease in the immunocompromised host. Among patients with predisposing factors, chronic glucocorticosteroid use, solid organ transplant, and advanced human immunodeficiency virus (HIV) disease are the most common underlying conditions.

DIAGNOSIS

The definitive diagnosis of blastomycosis requires a positive culture for *B. dermatitidis* from clinical specimens. A presumptive diagnosis is based on the finding of classic-appearing broad-based budding yeasts with doubly refractile cell walls compatible with *B. dermatitidis* on histopathologic examination of clinical specimens (Figure 178.1). Ten percent potassium hydroxide (KOH) is used to prepare wet specimens for examination, whereas fixed specimens are usually stained with hematoxylin and eosin, periodic acid–Schiff (PAS), or Gomori's methenamine silver (GMS) reagents. Serologic assays are of limited value in the diagnosis of blastomycosis. The complement fixation assay for serum antibody is highly cross-reactive and of little diagnostic value. Recent studies suggest that immunodiffusion or enzyme immunoassay (EIA) tests for A antigen of *B. dermatitidis* or antibody to more purified antigens have potential as serologic markers of disease. The *Blastomyces* EIA urine antigen assay is sensitive but nonspecific and gives false-positive

results among patients with active histoplasmosis, paracoccidioidomycosis, and penicilliosis. The blastomycin skin test antigen lacks sufficient sensitivity and specificity and should not be used as a diagnostic test.

TREATMENT

Presently, three drugs are approved for the treatment of blastomycosis: amphotericin B, itraconazole, and ketoconazole. Traditionally, amphotericin B has been the mainstay of therapy for all forms of blastomycosis, but studies and experience gained since the early 1990s indicate that ketoconazole, itraconazole, and fluconazole are highly effective alternative oral therapies. It was recently recommended that ketoconazole no longer be manufactured for systemic use because of hepatotoxicity concerns, so it is unclear if this compound will remain available to clinicians. More recently, voriconazole has emerged as an effective alternative to the older azoles, especially for patients with complicated disease involving the CNS. Although no comparative trials have been performed, itraconazole appears to have greater efficacy and less toxicity than either fluconazole or ketoconazole, and therefore is the oral agent of choice. In a recently published trial, 95% of patients with non-life-threatening, non-CNS blastomycosis were treated successfully with itraconazole, 200 to 400 mg daily for 2 to 6 months. This approximates the observed efficacy seen with amphotericin B. Clinical data regarding the use of fluconazole suggest similar efficacy of this agent, with at least 80% of patients responding to 400 to 800 mg daily for 6 months. Most patients with blastomycosis can be started on oral itraconazole, 200 mg daily and advanced by 100-mg increments at monthly intervals to a maximum of 400 mg daily in patients with persistent or progressive disease. In patients with more aggressive disease, an initial dose of 400 mg is appropriate. Therapy with any of the azoles should be given for a minimum of 6 months. Clinical experience with posaconazole is very limited in all forms of blastomycosis; however, based on in vitro susceptibility data, one would anticipate excellent clinical activity of this compound.

A formulation of amphotericin B is generally reserved for patients with overwhelming life-threatening and/or CNS disease, patients who are severely immunocompromised, and for those in whom oral therapy has failed. In selected patients, an induction dose of amphotericin B for a rapid fungicidal effect to gain control of the disease may be useful, followed by oral therapy with itraconazole for at least 6 months. For patients with CNS involvement, several reports suggest that fluconazole and voriconazole, two azoles with significant CNS penetration, are effective therapeutic agents among individuals who have had an initial favorable response to amphotericin B. There is substantial clinical experience but few published data concerning the use of the lipid formulations of amphotericin B in the treatment of blastomycosis. There are no data to suggest superior efficacy of these agents compared with conventional (deoxycholate) amphotericin B. However, the use of the lipid formulations of amphotericin B, at doses ranging from 3 to 6 mg/kg daily, to treat blastomycosis has become a standard approach in many developed countries where there is broad access to these compounds. Despite their greater expense, the lipid formulations are associated with significantly less nephrotoxicity than deoxycholate amphotericin B.

The treatment of acute pulmonary blastomycosis remains controversial. Many investigators suggest close observation without therapy in patients who are not immunocompromised; however, this approach has become less acceptable to many clinicians given the extensive safety and efficacy profile of the azole compounds. Available data suggest that most cases of acute pulmonary blastomycosis resolve spontaneously without therapy, although careful long-term evaluation of these untreated patients is important to monitor for evidence of active disease.

All patients with chronic blastomycosis should receive antifungal therapy. Cure rates of at least 90% should be expected, with relapse rates of less than 10%. Mortality is uncommon, and is usually seen among patients with extensive pulmonary involvement and acute respiratory distress syndrome (ARDS). A few patients, especially chronically immunocompromised individuals such as organ transplant recipients, patients receiving chronic glucocorticosteroid treatment, and patients with acquired immunodeficiency syndrome require long-term suppressive therapy to prevent relapse.

179. Coccidioidomycosis

Laurence F. Mirels and Stan Deresinski

BACKGROUND

Coccidioidomycosis, first described more than a century ago by Alejandro Posadas, is a disease of protean manifestations primarily endemic within ecologic zones of the Western Hemisphere characterized as the Lower Sonoran Life Zone with hot summers, few winter freezes, and annual rainfall of 10 to 50 cm. This includes areas in the southwestern United States (California, Arizona, western Texas, and highly localized areas of New Mexico, Nevada, and Utah), northern Mexico, and possibly Washington State, as well as scattered foci in Central and South America. Within these areas the incidence of coccidioidomycosis may vary significantly due to soil and climatic conditions that affect fungal and airborne dispersal, together with human behavior that increases exposure. There has been a marked increase in incidence in Arizona and California in recent years. *Coccidioides*, the etiologic agent of the infection, is a dimorphic fungus that grows in its soil reservoir in the mycelial (mold) phase. Under appropriate conditions, arthroconidia, the infectious spore form, disarticulate from mycelia and are carried airborne and inhaled, reaching the alveoli of the host. There the organism converts to the spherule phase, which reproduces by endosporulation with the subsequent rupture of the spherule releasing as many as 100 endospores, which subsequently, in turn, mature into spherules. Local control of the infection within the lung is the rule, but in some cases a chronic pulmonary infection may result or infection may spread within the thorax and/or distantly, via the lymphatics and bloodstream. Disseminated infection, especially when it involves the meninges, carries with it considerable potential for morbidity and mortality.

Coccidioides consists of two individual species, each with its own geographic distribution: *Coccidioides immitis* (found primarily in California) and *Coccidioides posadasii* (Arizona, Texas, and Mexico and areas of Central and South America). There are no substantive phenotypic differences between the species and the differentiation of one from the other is not routinely performed in the clinical laboratory. Similarly, no specific diagnostic, therapeutic, or prognostic ramifications have been attributed to the individual species.

PRIMARY INFECTION

Infection generally provides protection from subsequent exposure to the fungus. Approximately 60% of people acutely infected with *Coccidioides* spp. develop either no or minimal symptoms. After a usual incubation period of 7 to 21 days, the other approximately 40% of acutely infected people develop "flu-like" symptoms that may last weeks, including fever, sweats, myalgia, arthralgia, anorexia, weight loss, and fatigue. These constitutional symptoms are usually accompanied by a spectrum of respiratory complaints ranging from dry cough to symptoms such as pleuritic chest pain, tachypnea, and dyspnea. Reflecting this spectrum, the chest radiograph may be normal or may reveal scattered, patchy segmental infiltrates or dense lobar infiltrate(s) (Figure 179.1). Pleural effusion, usually minimal in volume, is noted in about 20%. In more severe cases, as may be seen following particularly heavy exposures or in infections of the immunocompromised, the chest radiograph may demonstrate diffuse reticulonodular infiltrates, a miliary pattern, or a pattern consistent with acute respiratory distress syndrome (ARDS). In fulminant cases, hemodynamic changes, including septic shock, may be present. In the acute phase, some patients develop a transient diffuse erythematous macular skin eruption, erythema nodosum, or, less commonly, erythema multiforme. These lesions are not the result of fungal dissemination but rather appear to represent immune reactions to the fungal infection, as does a self-limited arthritis ("desert rheumatism"), which may also occur. Development of erythema nodosum trad-

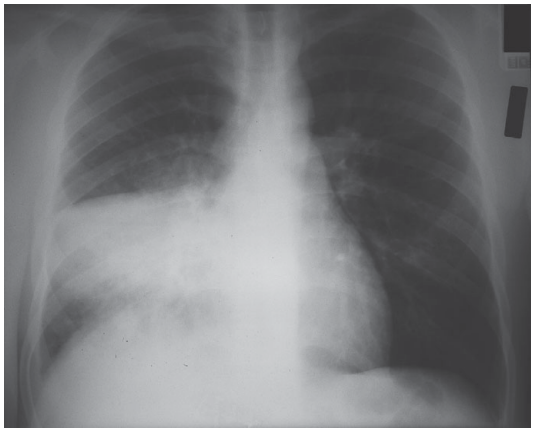

Figure 179.1 Primary pulmonary coccidioidomycosis. This 18-year-old male Pacific Islander presented with community-acquired pneumonia, and this chest radiograph shows a dense right middle lobe infiltrate. Coccidioidomycosis was suspected as the patient had recently moved to California's Central Valley to attend college, demonstrating the importance of the travel history in such settings. He was treated with fluconazole for 6 months and recovered uneventfully.

itionally has been associated with subsequent successful resolution of disease.

Because the presentation of acute coccidioidomycosis resembles that of many other respiratory infections, obtaining a travel history placing the patient in an endemic area in the weeks prior to onset of illness can greatly expedite the diagnosis and emphasizes the importance of a detailed exposure history for all such patients, not only for consideration of coccidioidomycosis but for other endemic mycoses or even more exotic infections. Although no findings are unique to acute coccidioidomycosis, those that tend to suggest this diagnosis include unexpectedly pronounced fever, fatigue, and weight loss and immune phenomena such as erythema nodosum. Eosinophilia may occur. Radiographic hints, when present, include a thin-walled cavity, nodule formation at sites of infiltrates, and pronounced hilar adenopathy, but these findings are nonspecific. Usually the clinical picture is indistinguishable from other causes of community-acquired pneumonia; patients are frequently prescribed one or more courses of antibacterial antibiotics and the absence of a response may be an important diagnostic clue. Some cases are serendipitously discovered when a routine sputum culture yields growth of the fungus.

The infection resolves spontaneously without treatment in the vast majority of patients. Some symptoms, particularly fatigue, may take weeks and in some cases, months to completely resolve. Persisting radiographic residua in the form of pulmonary nodules or cavities develop in approximately 5% of all infected individuals. Viable organisms may persist and remain inactive for decades after resolution of the primary infection. Reactivation may, however, occur, particularly in patients who subsequently become immunosuppressed.

CHRONIC PULMONARY AND DISSEMINATED COCCIDIOIDOMYCOSIS

The development of chronic active pulmonary infection or clinically important dissemination following primary infection is fortunately uncommon, occurring in just several percent of cases. Certain characteristics define individuals or groups with a greatly increased risk of dissemination or progressive pulmonary infection (Table 179.1) and in whom these complications tend to be more refractory to treatment. Included are those who are overtly immunocompromised due to underlying illness (e.g., human immunodeficiency virus/acquired immunodeficiency virus [HIV/AIDS], lymphoma) or due to receipt of immunosuppressants (e.g., patients who have undergone transplantation or are receiving treatment for rheumatologic disorders). Recently, several patients with disseminated coccidioidomycosis and abnormalities in their interferon (IFN)-γ–interleukin (IL)-23–IL-12 axis, as well as at least one patient with hyper-IgE syndrome have been described. For reasons that remain unexplained, Filipinos and African Americans are at increased risk of dissemination of their infection. Pregnant women (especially in the third trimester) and women in the immediate postpartum state often have great difficulty controlling their infections, although it has been suggested that flares of disease after delivery may represent a form of immune reconstitution inflammatory syndrome. It is not certain that transplacental infection of the fetus occurs and the very rarely

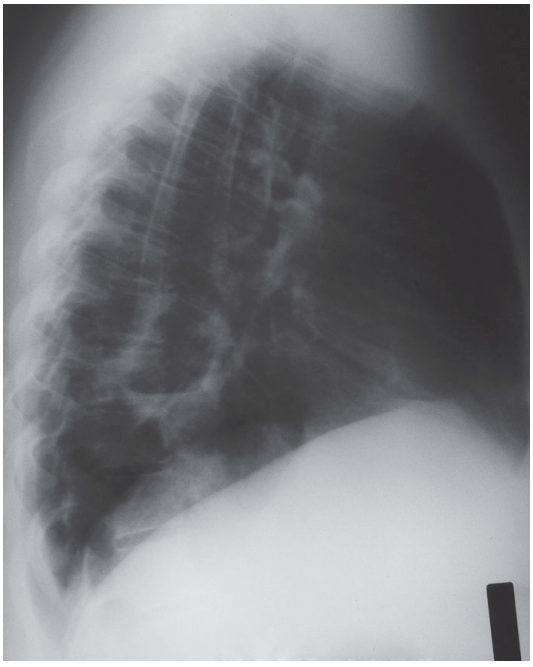

Figure 179.2 Chronic cavitary pulmonary coccidioidomycosis. Chest radiograph of a 21-year-old Hispanic woman with type II diabetes and known chronic cavitary coccidioidomycosis. She presented with 1 week of low-grade fever and increasing productive cough. Her lateral chest radiograph shows a chronic cavity with thickened walls and an air–fluid level consistent with bacterial superinfection. She responded to a 14-day course of amoxicillin–clavulanate and remained on fluconazole.

observed neonatal infections are likely the result of aspiration of amniotic fluid or vaginal secretions. Diabetes mellitus, particularly if poorly controlled, has been associated with the development of chronic cavitary pulmonary disease and possibly also carries an increased risk of dissemination. It is also likely that exposure to very large inocula of arthroconidia may result in severe disease, including dissemination, even in previously healthy individuals without known risk factors.

Following primary infection, a small proportion of individuals go on to develop persistent infections confined to the lung. Such patients may display pulmonary cavities with walls that appear thicker than that seen in classical coccidioidal cavities (Figure 179.2) and chronic symptoms of dry or productive cough, chest pain, shortness of breath, and hemoptysis, each of which may wax and wane. A distinct subgroup will develop a destructive, progressive fibrocavitary pulmonary infection with fibrotic changes in the lung parenchyma and bronchiectasis. In addition to the symptoms mentioned earlier, these patients are often plagued by constitutional symptoms such as fever and weight loss, which may progress to cachexia. Complement-fixing antibody (CFA) titers in this group tend to be somewhat high. Complications associated with cavities include bacterial superinfection (recurrent), fungus ball formation (due to *Coccidioides* spp. or other fungi), and rupture into the pleura with (hydro-)pneumothorax, empyema, and/or bronchopleural fistula. In the absence of profound immunocompromise, chronic pulmonary disease is infrequently associated with extrapulmonary foci of infection.

Disseminated disease usually becomes clinically evident within 6 months of the initial infection. Evaluation of the patient may reveal involvement of only a single anatomic site or of multiple organ systems. Dissemination may occur in patients who were asymptomatic with their primary infection and, in those with symptomatic primary infections it is common for pulmonary symptoms and findings on chest radiograph to have resolved completely at the time of presentation with extrathoracic disease. Both of these circumstances tend to obscure the diagnosis of coccidioidomycosis.

Skin lesions are the most frequently recognized manifestation of extrapulmonary dissemination. Lesions may be single or numerous, range in size from several millimeters to many centimeters in diameter, and, even in the same patient, may take on a variety of forms, including smooth to verrucous papules, plaques, ulcers, or pustules (Figure 179.3A). Bone is a frequent site of dissemination with vertebrae, often numerous, being particularly favored. The cranial vault, pelvis, ribs, tibia, feet, metacarpals, and metatarsals are other common targets. Bone lesions may be asymptomatic or associated with pain that may be described by the patient as constant and gnawing. These lesions are usually lytic, may be highly destructive, and may be accompanied by extensive adjacent soft-tissue involvement. Bone scans and magnetic resonance imaging (MRI) are particularly useful modalities for identifying bone lesions and for evaluating the extent of bone and neighboring soft-tissue involvement, respectively (Figure 179.4). Dissemination to joints is not infrequent and may be heralded by rapid or more insidious development of findings typical of septic arthritis. The knee is affected most frequently followed by joints of the ankle and foot, wrist, hands, and the elbow. The resultant

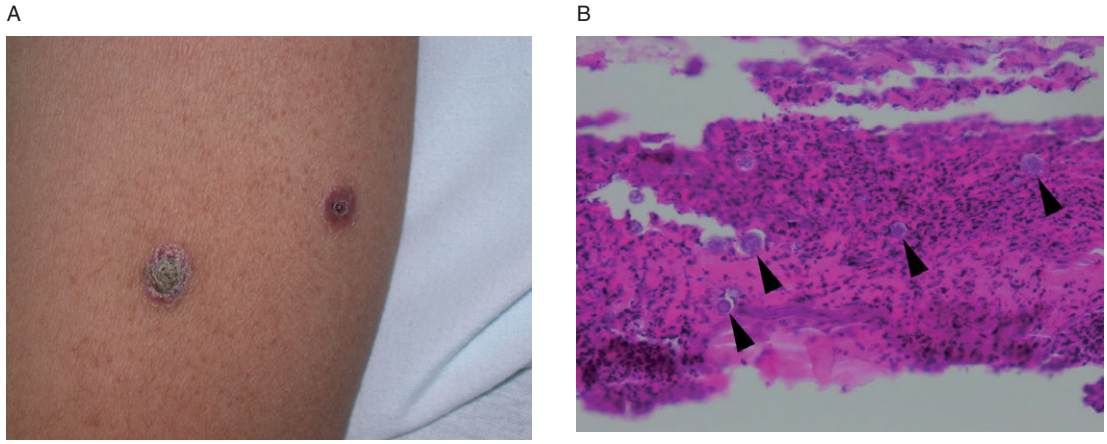

Figure 179.3 Disseminated coccidioidomycosis, skin lesions. (**A**) This 26-year-old previously healthy Filipino man presented with coccidioidomycosis featuring numerous skin lesions of varying size and appearance. This photograph shows two suspicious lesions on the arm, each measuring ~5 mm in diameter. (**B**) Photomicrograph of a punch biopsy of the skin which was taken from the margin of the verrucous lesion shown in the adjacent photograph. There is significant lymphocytic infiltration, and numerous spherules are evident (several of which are highlighted by arrowheads) thus making the diagnosis of disseminated coccidioidomycosis. (Original magnification, 400×, tissue stained with hematoxylin and eosin.) This patient made a full recovery and continues on itraconazole.

synovial proliferation may be mistaken for rheumatoid arthritis by the arthroscopist. Pelvic joints may be involved, intervertebral disks are usually spared. Arthrocentesis may lead to the diagnosis; synovial biopsy, however, offers a higher yield. Subcutaneous abscesses may represent primary sites of dissemination but often prove to have resulted from suppuration of a lymph node or extension of pus from a deeper (sometimes surprisingly distant) focus by formation of a sinus tract.

The central nervous system is a major site of dissemination and infection at this site is most likely to result in permanent disability or death. *Coccidioides* spp. typically cause a chronic granulomatous meningitis, most often involving the basilar meninges of the brain and those of the upper spinal cord (Figure 179.5). Central nervous system involvement generally occurs within months of the primary infection but occasionally is seen after much longer intervals. Symptoms may be abrupt or insidious in onset and progress inexorably at a tempo that varies from patient to patient. If the underlying disease remains untreated it virtually always will lead to death within 2 years. Patients complain primarily of headache with anorexia, nausea, vomiting, visual changes, generalized weakness, and ataxia as possible associated symptoms (often being secondary to the development of hydrocephalus). Progressive lassitude and altered mentation often are the dominant findings. Furthermore, patients may have only very mild symptoms even in the face of impressive cerebrospinal fluid (CSF) findings and meningeal signs are often subtle or absent. Nonetheless, routine lumbar puncture is not indicated in the absence of potentially suspicious signs or symptoms. Hydrocephalus is a frequent complication of coccidioidal meningitis and may even develop late and in the face of appropriate, otherwise effective therapy. Abscess formation, cranial nerve involvement, myelitis, arachnoiditis, and syrinx formation, as well as cerebral vasculitis are also occasionally seen.

Other anatomic sites involved with some regularity in disseminated disease include lymph nodes, liver, spleen, male and female genitourinary tracts, peritoneum, pericardium, thyroid, and the eye.

DIAGNOSIS

The diagnosis of coccidioidomycosis is best made by direct examination of tissues or secretions for the presence of characteristic fungal forms (Figure 179.3B) and by culture, which usually requires 2 to 6 days for recovery of the organism. Amplification with subsequent sequencing of DNA encoding 18S rRNA has successfully identifed fungal pathogens in tissue and may prove useful in coccidioidomycosis. Blood cultures may rarely be positive and only in individuals, usually

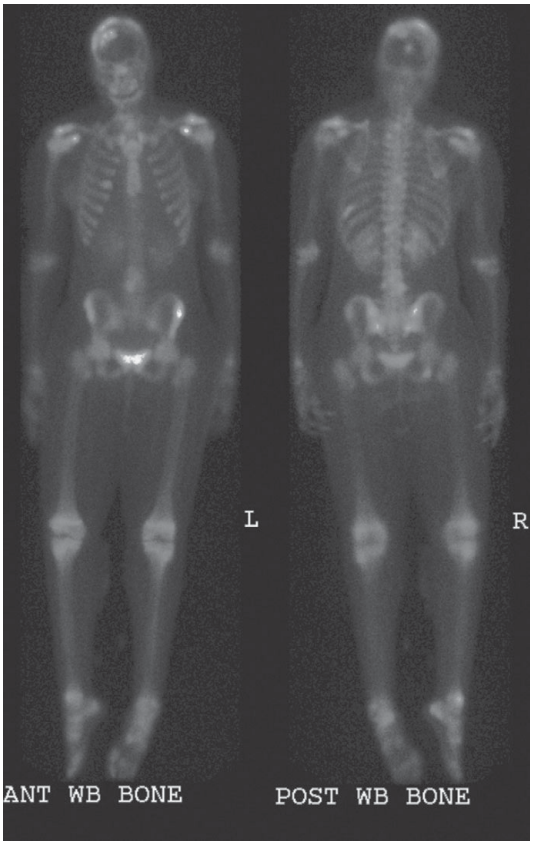

Figure 179.4 Disseminated coccidioidomycosis, bone lesions. This 14-year-old healthy African-American adolescent presented with widely disseminated coccidioidomycosis. These delayed whole-body three-phase bone scan images demonstrate abnormal uptake indicative of a multitude of bone lesions that were subsequently verified by magnetic resonance imaging, computed tomography, or plain film: vertebral lesions are seen throughout the length of the spine; there are multiple lesions of the calvaria; lesions affecting the right sixth rib, the left tenth rib, both shoulders, the right ankle, and the right ischium are readily appreciated. Of note, only her shoulder and lower spine lesions were symptomatic. She was successfully treated medically with 1 month of intravenous amphotericin B, which was transitioned to itraconazole. She continues on itraconazole.

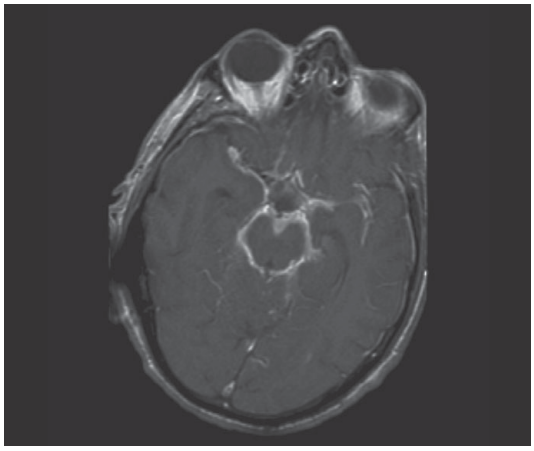

Figure 179.5 Coccidioidal meningitis. This 48-year-old Hispanic man with type II diabetes presented with headache and obtundation. This axial T1-weighted magnetic resonance image taken after the administration of contrast shows abnormal enhancement of the leptomeninges at the base of the brain. Hydrocephalus was treated by placement of a ventriculoperitoneal shunt, and a lumbar reservoir was placed to facilitate delivery of intrathecal amphotericin, which was given along with fluconazole. He made a full recovery and now continues on fluconazole alone.

severely immunocompromised, with severe acute dissemination of infection. Urine cultures may very rarely be positive. When culture samples are submitted in a case of suspected coccidioidomycosis, laboratory personnel should be notified in order to reduce the risk of transmission in that setting. Serologic tests, such as immunodiffusion and enzyme-linked immunosorbent assays, that identify anticoccidioidal immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies in serum and IgG in CSF are useful. The magnitude of the CFA titer, which is a measure of the amount of anticoccidioidal IgG antibody, has the valuable property of correlating with the extent of disease so that 80% or more of patients with dissemination to more than one site will have serum titers $\geq$1:16. Furthermore, changes in the CFA titer are useful in guiding therapeutic decisions – a falling titer is an indication of response to antifungal administration.

Antibody testing may be negative during the first weeks of infection and, if coccidioidomycosis is still suspected, repeat testing is indicated. Positive tests may revert to negative with successful control of infection. A positive IgM anticoccidioidal antibody test together with a negative IgG test may reflect very recent infection and, once again, repeat testing will clarify the diagnosis. If repeated and the pattern persists, the IgM test is likely falsely positive, although early initiation of fluconazole therapy may produce the same result. False-negative antibody results occur in immunocompromised patients, such as immunosuppressed transplant recipients and patients with immunodeficiency syndrome (among whom the incidence of coccidioidomycosis has dramatically decreased with the widespread use of effective

antiretroviral therapy). A coccidioidal antigen test is available in a commercial laboratory, but its characteristics remain to be fully defined.

In patients with meningitis, analysis of CSF demonstrates a predominantly mononuclear pleocytosis (usually 50 to 500 cells/mm^3, with the percentage of polymorphonuclear leukocytes present tending to decrease over time), elevated protein (usually 100 to 500 g/dL), and low glucose – a picture that is compatible with other etiologies, including tuberculosis. A marked increase in protein concentration may indicate the development of an impairment of CSF flow and reabsorption. Eosinophils may be present (usually in a range of 1% to 10% of CSF white blood cells) and, in patients with an appropriate travel history (including one that does not suggest the possibility of cysticercosis or of *Angiostrongylus* infection), coccidioidomycosis should be considered. Culture of CSF yields the organism in only a minority of cases, but IgG antibodies directed at coccidioidal antigens may be detected in the fluid in >90% of cases. Nucleic acid amplification-based tests for the detection of *Coccidioides* spp. in body fluids or tissue specimens may ultimately prove to be an important advance in the diagnosis of coccidioidomycosis, but they are not yet available for general use.

Human-to-humn transmission of *Cocccidioides* spp. does not occur and patient isolation is not indicated. Infection has, however, been transmitted to solid organ transplant recipients via the transplanted organ. Objects such as linens, bandages, and casting materials contaminated with body fluids containing the organism (e.g., pus or sputum) are capable of supporting its conversion to the infectious mycelial form over a period of several days at room temperature. All such fomites should therefore be collected daily and sterilized using standard hospital practices for handling biologic waste.

TREATMENT

General considerations

Table 179.2 summarizes treatment recommendations.

Azole antifungal agents have, in most instances, supplanted the use of amphotericin B in the treatment of coccidioidomycosis. Amphotericin B is, however, often preferred as initial therapy when rapid control of the disease is imperative, such as in life-threatening, fulminant, or rapidly progressive infections. Once control of the infection is achieved, therapy may be transitioned to use of an azole, usually fluconazole. Amphotericin B is also preferred during the first trimester of pregnancy due to the teratogenicity of prolonged high-dose fluconazole (and presumably other members of the class) administration during this period. While there is no evidence that a lipid formulation of the polyene is more effective, one is preferred because of lesser associated toxicity than seen with the deoxycholate preparation. Whether an azole is used from the outset or for later replacement of amphotericin B, either fluconazole or itraconazole may be safely chosen, but the former has the distinct advantages of reliable bioavailability and fewer pharmacokinetic interactions with other medications, making it the preferred agent. Voriconazole and posaconazole are each active in vitro against *Coccidioides* spp. and, while their role in initial therapy has not been systematically evaluated, published clinical experience indicates that they have a place in salvage therapy. While there is no value in therapeutic drug monitoring in patients receiving fluconazole in the absence of changing renal function, the erratic bioavailabilities of itraconazole, voriconazole and posaconazole make such testing potentially useful. The echinocandins, which have in vitro activity when evaluated by a nonstandard method, have been used as part of salvage therapy in combination with other antifungals and it is not possible to judge their efficacy in coccidioidomycosis. IFN-γ, when administered in conjunction with antifungals, has a role in some patients with genetic mutations affecting the IFN-γ–IL-23–IL-12 axis. It has also been administered to a small number of patients with progressive therapy-resistant infection in the absence of defects in that axis with clinical improvement in some, but its use remains experimental (and very expensive).

Uncomplicated primary pulmonary infection

In the majority of cases, primary infection with *Coccidioides* is self-limited and, given the continued absence of contrary evidence, antifungal therapy is not routinely warranted. Patients considered at increased risk of complications are, however, potential treatment candidates. In addition to those listed in Table 179.1, risk factors in this setting may also include pre-existing cardiopulmonary disease, chronic renal insufficiency, and severe manifestations of infection such as extensive pulmonary involvement, intense night sweats lasting >3 weeks, loss of >10% of body

Table 179.2 Summary of treatment recommendations

Primary pulmonary
No dissemination risk: No treatment or fluconazole, 400 mg daily, or itraconazole, 200 mg BID, for approximately 3–6 mo or for 3 mo after complete resolution of clinical infection. All patients should be followed closely
Dissemination risk or severe disease: fluconazole, ≥400 mg daily, or itraconazole, ≥200 mg BID, for approximately 3–6 mo, including ≥3 mo after resolution of clinical infection
Pulmonary cavity (uncomplicated) or fibrocavitary disease
Observation or fluconazole, 400 mg daily for ≥6–12 mo, and assess for response. Individualized management of complications. Surgical resection in selected cases
Progressive pulmonary or disseminated (nonmeningeal)
Immediately life threatening: amphotericin B lipid formulation, 3.0–5.0 mg/kg/d; consideration given to transition to fluconazole or itraconazole when disease is controlled. Alternatively, fluconazole, ≥400 mg daily, or itraconazole, ≥200 mg BID. The duration of therapy is usually at least 2 yr; some patients may require lifelong therapy. Individualized management depending on site(s) of involvement
Slowly progressive or stable: fluconazole, ≥400 mg daily, or itraconazole, ≥200 mg BID. The duration of therapy is usually at least 2 years; some patients may require lifelong therapy. Individualized management depending on site(s) of involvement
Meningitis
Fluconazole, ≥400 mg daily (many advocate starting dose of ≥800 mg), or itraconazole ≥200 mg BID (doses as high as 600 mg BID have been used, recommend checking serum levels)
or
Amphotericin B directly into cerebrospinal fluid (usually with an oral triazole dosed as above) transitioned to oral azole alone (usually dosed at no lower than 400 mg total daily)
Patients must be evaluated frequently for the emergence of complications and serial CSF analyses must be performed to document response to therapy, particularly early in the course
Due to the high relapse rate, patients with coccidioidal meningitis usually continue on antifungal therapy for life
HIV-infected patients
All HIV infected patients with CD4+ lymphocyte count ≤250 cells/mm^3 with any form of coccidioidomycosis should receive antifungal therapy. If the infection is immediately life threatening, initial treatment with amphotericin B is preferred. With stabilization, fluconazole or itraconazole may be used, with careful attention to drug interactions with some antiretrovirals. Consider discontinuation if nonmeningeal disease, therapy has been prolonged and the CD4+ count is stably >250 for at least 6 mo. For meningeal disease, lifelong antifungal treatment regardless of CD4+ count achieved
Pregnant patients in first trimester
Amphotericin B lipid formulation, 3.0–5.0 mg/kg/d

Abbreviations: HIV = human immunodeficiency virus; CSF = cerebrospinal fluid.

weight, persistent hilar adenopathy (although a recent study found only a nonstatistically significant trend risk for patients with mediastinal lymphadenopathy), and CFA ≥16. Thus, each patient requires individualized assessment.

If it is elected to treat, fluconazole, 400 mg once daily, is the preferred choice (except in those in the first trimester of pregnancy who should receive amphotericin B). Itraconazole, 200 mg twice daily, is an alternative but bioavailability is variable and drug interactions are many. The optimal duration of therapy is unknown but a minimum of 3 months is often recommended. Longer durations may be indicated in others, including those with significant ongoing immunocompromise and those whose high CFA titers fail to fall during therapy.

Whether treated or not, it is imperative that patients be evaluated at intervals for as long as 2 years to assure that infection has successfully resolved and to detect complications as early as possible. Evaluations should include a complete review of systems, physical examination, serum CFA titer, and, as appropriate, repeat radiographic studies or cultures. For those receiving an azole antifungal, monitoring for side effects and periodically obtaining routine bloodwork (e.g., liver function tests, electrolytes, complete blood count) are advisable.

Progressive pulmonary or nonmeningeal disseminated infection

Amphotericin B is often recommended for initial treatment of patients with rapidly progressive pulmonary or disseminated infection that is immediately life threatening. Nonmeningeal coccidioidomycosis that is progressing at a more indolent pace, however, is generally treated with

an orally administered azole. In the United States ketoconazole, despite having demonstrated efficacy in the treatment of coccidioidomycosis, has been supplanted by other agents, with fluconazole being the preferred choice. In patients who fail fluconazole therapy, other triazoles may still prove effective.

In general, treatment of nonmeningeal disseminated or progressive pulmonary coccidioidomycosis should continue for at least 2 years or for 1 year after the infection appears to have resolved completely, whichever is longer. As many as one-third of patients may relapse after discontinuation of even such prolonged courses. For this reason, there is a critical need for continued, long-term, careful observation of patients who are no longer receiving antifungal therapy. Patients with AIDS should continue to receive an antifungal agent until their CD4+ T-cell count remains >250 cells/mm^3 for at least 6 months.

Meningitis

A multicenter study demonstrated a response (defined as resolution of ≥40% of baseline abnormalities) rate of 79% with a daily dose of fluconazole of 400 mg given for a median duration of 37 months in the treatment of coccidioidal meningitis. Daily doses of fluconazole of 800 mg or greater may possibly be associated with an improved early response to therapy but also with a greater incidence of adverse reactions. While the available data are more limited, itraconazole, at total dosages of 400 mg daily or higher, may possibly have similar efficacy. Although apparent cures have been reported, relapse after discontinuation of drug administration is extremely frequent and lifelong suppressive therapy is indicated. Intrathecal amphotericin B administration should be considered in patients who fail azole therapy – systemic azole administration is generally continued when this course is taken. Corticosteroid administration may be considered in patients whose meningitis is complicated by the development of cerebral vasculitis, although unequivocal evidence of benefit is lacking.

Patients undergoing treatment for meningitis require close observation. Evaluations should include a review of systems, physical examination, lumbar puncture to follow the opening pressure, cell count, protein, glucose, and CFA titer, and, potentially, radiographic imaging. Evidence of disease progression necessitates immediate intensification of therapy (minimally a trial of an increased dose of the current therapy or conversion to an entirely different antifungal and, in some cases, consideration of intrathecal administration of amphotericin). The occurrence of complications may require urgent intervention. One frequently encountered example is the development of hydrocephalus. The treatment of coccidioidal meningitis is often complex and should probably be attempted only by, or in close collaboration with, clinicians experienced in its management.

The role of direct injection of amphotericin B into the CSF space remains poorly defined. When used, injection is accomplished via the lumbar, lateral cervical, or cisternal route by direct puncture or through the use of implanted devices such as an Ommaya reservoir. The latter may be implanted for injection into either a lateral cerebral ventricle or the lumbar space. CSF flow patterns should be defined by radionuclide or dye studies when determining the optimal route for the delivery of amphotericin to the sites of central nervous system infection because CSF flow may be disrupted by blockages or loculations.

When administering intrathecal amphotericin by the lumbar route, some clinicians prefer using the "hyperbaric" technique, which allows delivery of the drug in high concentration to the basilar meninges, where the major burden of infection is ordinarily found. In addition, the rapid removal of drug from the lumbar area theoretically decreases the likelihood of some of the possible local complications induced by amphotericin, such as radiculitis, myelitis, arachnoiditis, and spinal artery thrombosis. Concomitant azole therapy is usually maintained in patients receiving intrathecal amphotericin.

The development of hydrocephalus, either communicating or noncommunicating, occurs frequently and should be suspected when the patient's neurologic status deteriorates; nausea, vomiting, ataxia, or weakness develops; or if the CSF protein concentration increases to high levels. Hydrocephalus should be managed by the placement of a CSF shunting device, but a change in antifungal therapy may not be warranted. Central nervous system vasculitis may complicate coccidioidal meningitis. Although no comparative data exist, some clinicians suggest administration of corticosteroids along with maximal antifungal therapy in patients with this complication.

Other infections

In the absence of immunosuppressive disease or therapy, antifungal treatment is not required in the case of a stable, solitary pulmonary nodule. Coccidioidomycosis of the airways may be effectively treated with an azole.

Chronic pulmonary cavities respond poorly to antifungal therapy and, if asymptomatic, may best be left untreated. Complications include bacterial superinfections and hemoptysis. On occasion, hemoptysis may be the result of the development of a mycetoma. Cavitation may progress even in the face of chemotherapy. These complications are potential indications for surgical intervention. Rarely, a coccidioidal cavity may rupture into the pleural space, resulting in pyopneumothorax. This complication should be managed surgically with concomitant administration of an antifungal agent.

Chronic progressive fibrocavitary pulmonary infection requires prolonged antifungal therapy; surgical resection of the affected tissues may be of value in some cases in which the disease is sufficiently localized.

The musculoskeletal system is a common site of involvement in cases of disseminated infection. In addition to antifungal chemotherapy, surgical debridement may be warranted in some cases of osteomyelitis. Synovectomy may be beneficial in the management of chronic coccidioidal arthritis.

BIOLOGIC RESPONSE MODIFIERS AND DISEASE-MODIFYING AGENTS IN PATIENTS WITH RHEUMATOLOGIC DISEASE

In the patient with rheumatic disease receiving biologic response modifiers (BRMs) and/or classical disease-modifying agents (DMAs) who develop coccidioidomycosis, recent recommendations suggest that, along with initiation of antifungal therapy, these may be continued, with careful repeated evaluation. In patients who develop pulmonary infection, BRMs and DMAs should be at least temporarily discontinued but may be resumed after resolution of the infection. BTMs and DMAs should be discontinued in patients with disseminated infection. It may be reasonable to extend this approach to patients whose infection antedates the need for BRMs and/or DMAs. Whether to administer prophylactic antifungals in the patient with past, but now inactive coccidioidomycosis is uncertain but may be considered.

PROPHYLAXIS

It has been recommended that individuals inadvertently exposed to potential aerosols of *Coccidioides* spp. in the laboratory receive fluconazole or itraconazole for 6 weeks as prophylaxis. Prophylaxis, although not invariably successful, can also be considered for transplant recipients without active infection but with detectable serum antibody to coccidioidal antigen or with a past history of coccidioidomycosis.

180. *Pneumocystis jirovecii* (*carinii*)

Shelley A. Gilroy and Nicholas J. Bennett

BACKGROUND

Pneumocystis jirovecii (pronounced "yee-row-vet-zee"), formerly known as *Pneumocystis carinii*, is an opportunistic pathogen that causes pneumonia in the immunocompromised individual. The initials "PCP" stood for *Pneumocystis carinii* pneumonia but were kept for ease of use after the organism was renamed. Disease occurs when both cellular and humoral immunity are impaired. Serologic studies have shown that *Pneumocystis* has a worldwide distribution but the prevalence of antibodies to specific antigens varies among different geographic regions. PCP first came to attention when it caused interstitial pneumonia in severely malnourished and premature infants in Central and Eastern Europe during World War II. Prior to the acquired immunodeficiency syndrome (AIDS) epidemic in the 1980s, fewer than 100 cases were reported annually in the United States. PCP is one of several life-threatening opportunistic infections in patients with human immunodeficiency virus (HIV) infection worldwide and is still the most common AIDS-defining illness in patients with advanced HIV infection. The decline in the number of PCP cases in the United States occurred after the introduction of anti-pneumocystis prophylaxis in 1989 and highly active antiretroviral therapy (HAART) in 1992. In patients without HIV infection, the incidence of PCP has increased in those being treated with immunosuppressive and chemotherapeutic agents and in hematopoietic stem cell (HSCT) and solid organ transplant recipients.

The taxonomic classification of the *Pneumocystis* genus and the organism's name has changed throughout the years. In the 1980s, biochemical analysis identified the organism as a unicellular fungus. *Pneumocystis jirovecii* is found in three distinct morphologic stages: the trophozoite, in which it often exists in clusters, the sporozoite (precystic form), and the cyst, which contains several intracystic bodies (spores). The cyst is the diagnostic form of *P. jirovecii* and stains with Giemsa, Papanicolau, and Grocott methenamine silver nitrate (GMS) and immunocytochemical techniques using monoclonal antibodies. Giemsa- and Papanicolau-stained smears show indirect evidence of *P. jirovecii* infection by the demonstration of foamy exudates in the form of alveolar casts.

The environmental source for *Pneumocystis* is unknown. Studies in animals and humans suggest that it is transmitted by the airborne route. The organism can be found in the respiratory tract of hospitalized patients with viral or bacterial infections and healthy individuals without pneumonia. These individuals may serve as a reservoir for infection to susceptible hospitalized patients. The time necessary from colonization to infection is unknown. Once *Pneumocystis* enters the lungs it attaches to the alveoli. Alveolar macrophages are the first line of defense and are responsible for clearing the organism from the lung. This function is impaired in patients with HIV or cancer and in transplant recipients receiving immunosuppressive therapy. Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1), proinflammatory cytokines, have been shown to be important in host defenses against the organism in the early stages of infection. As the host defenses become compromised, *Pneumocystis* organisms proliferate and fill alveolar lumens, subsequently leading to interstitial plasma pneumonia.

Extrapulmonary *Pneumocystis* infection is rare. Dissemination may occur via direct spread, hematogenous spread, or via lymphatic vessels in the absence of pneumonia. It can occur in HIV-infected patients receiving aerosolized pentamidine for prophylaxis. The most common organs or tissues infected are the lymph nodes, spleen, liver, bone marrow, and the small intestine.

CLINICAL MANIFESTATIONS

PCP is an AIDS-defining illness, typically occurring in HIV-infected patients not taking HAART, with a T-helper cell count (CD4) less than 200 cells/mm^3. Symptoms include insidious onset of dyspnea with a dry cough, fever, diarrhea, and weight loss. Acute dyspnea with chest pain may indicate a pneumothorax. Physical examination typically reveals tachypnea, tachycardia, and fever with normal findings or mild crackles or rhonchi on lung auscultation. Oral thrush or oral hairy leukoplakia may also be present. A resting PaO_2 of less than 80 mm Hg occurs in 80% of cases. Desaturation with exercise is a highly sensitive marker of PCP, even if the PaO_2 is normal. A clinical picture of PCP in HIV-infected patients with a high CD4 count should prompt consideration of immune reconstitution inflammatory syndrome (IRIS), defined as a clinical deterioration caused by restoration of a patient's capacity to mount an inflammatory immune response against infectious and noninfectious agents once HAART has begun.

In children early signs are poor feeding, diarrhea, and coryza. Physical findings include nasal flaring, intercostal retraction, and cyanosis.

Immunocompromised patients without AIDS typically present with acute respiratory insufficiency or shorter duration of illness and fewer days of dyspnea and fever. PCP can occur with or without lymphopenia or low CD4 counts.

The most significant risk factors for PCP are defects in cell-mediated immunity, prolonged glucocorticoid use, cancer (particularly hematologic malignancies), HSCT, rheumatologic diseases, severe combined immunodeficiency, and severe malnutrition. The most common chemotherapeutic drugs associated with increased risk of PCP are fludarabine, vincristine, and cyclophosphamide. Patients receiving biologic agents, particularly alemtuzumab and the TNF inhibitor infliximab, are also at risk for infection.

In early mild disease the chest radiograph will be normal. High-resolution computed tomographic scanning (HRCT) is more useful.Typical findings are diffuse micronodules, patchy ground-glass, symmetric or asymmetric opacities, reticulation, septal thickening, and/or airspace consolidation (Figure 180.1). Apical interstitial infiltrates and pneumothorax occur more often in patients receiving prophylactic treatment with aerosolized pentamidine. Solitary or multiple nodules, which may cavitate, and pneumatoceles are less common. Pleural effusions and intrathoracic adenopathy are rare.

Figure 180.1 High-resolution computed tomographic image of the upper lung zones demonstrates diffuse micronodules, patchy ground-glass opacities, as well as some fine reticulation, all suggestive of an interstitial process consistent with P*neumocystis* pneumonia. (Courtesy of Frederic Hellwitz, MD, Department of Radiology, Albany Medical College, Albany, NY). Reprinted with permission from Thieme Publishers.

DIAGNOSIS

Pneumocystis has no effective culture-based test and the diagnosis, if suspected on clinical grounds, usually relies on obtaining invasive respiratory specimens. Tests on routine sputum specimens are insensitive and should not be performed, although induced sputum (performed with a respiratory therapist after inhalation of nebulized hypertonic saline) is about 50% sensitive. The sensitivity varies but approaches 90% in some institutions depending on technique proficiency and the experience of the laboratory. A negative result would not rule out PCP. Optimal testing requires bronchoscopy and bronchiolar lavage. Lung biopsy is diagnostic.

The classic histology findings are "foamy alveolar casts," in which there is proteinaceous fluid within the alveoli (Figure 180.2). With a silver stain such as GMS, pneumocystis can be visualized as teacup-shaped organisms (Figure 180.3). Immunofluorescence techniques such as direct fluorescent antigen (DFA) can also be employed and are sensitive and specific. PCR testing is not readily available and is more difficult to interpret (carriage versus infection) due to its increased sensitivity.

In certain clinical settings, it may not be practical or safe to obtain invasive specimens, and noninvasive specimens are preferred. Serologic testing specific to PCP is available, but cannot reliably distinguish between past and present infection. The majority of people will, at some

point, become colonized with *Pneumocystis* and seroconvert, although some efforts have been made towards using the specific antibody titers or responses to specific proteins as being more indicative of active infection.

The *Pneumocystis* cell wall contains the same 1–3 β-D-glucan (BDG) as candida and aspergillus, and an assay for serum levels of BDG (known as Fungitell commercially) has proven to be sensitive and specific for PCP, when appropriate cutoff levels are used. Because of the cross-reactivity of the assay to multiple fungi, interpretation of assay results should be done in the clinical context of the patient. PCP may be associated with somewhat higher levels of BDG than are seen in invasive candidiasis or aspergillosis. In patients with non-HIV PCP, and in children with PCP, levels tend to be higher than in HIV-associated PCP but there are no levels at which PCP can be reliably ruled in or out. In all cases, serum levels can be used to track response to treatment.

TREATMENT AND PROPHYLAXIS

Recommended antimicrobial regimens are detailed in Table 180.1. The mainstay treatment of PCP is trimethoprim–sulfamethoxazole. The dosing is usually 15–to 20 mg/kg/day in three divided doses for 14 to 21 days, orally or intravenously depending on severity of illness. Adjunct corticosteroids have been shown to have benefit in HIV-associated PCP with significant hypoxemia (an alveolar–arterial oxygen gradient of greater than 35 mm Hg, or an arterial oxygen partial pressure of 70 mm Hg on room air). The role of steroids is in blunting the immune reaction to microorganism degradation which can result in an acute respiratory distress syndrome-like process. Guideline dosing for methylprednisolone is 40 mg twice daily on days 1–5, 40 mg once a day on days 6–10, 20 mg once a day on days 11–21.

Alternative medications, for instance in the case of allergy to sulfa-based antibiotics, include atovaquone, pentamidine, and dapsone, of which the latter is usually given in combination with trimethoprim or pyrimethamine and leucovorin.

Trimethoprim–sulfamethoxazole, pentamidine, or dapsone can all be used for prevention of PCP (Table 180.2). Prophylaxis is recommended for high-risk individuals, particularly those with HIV infection and CD4+ T-cell counts less than 200 (or a history or previous PCP regardless of CD4 count). Other causes of immune suppression or deficiency also increase the risk of *Pneumocystis*, to varying degrees. Neonates with severe combined immune deficiencies (SCID) and recipients of bone marrow transplants are at particularly high risk. Individuals with CD40 ligand deficiency are associated with an increased risk of PCP and should be placed on prophylaxis. Interestingly, although the 22q11 deletion syndrome (also known as DiGeorge or velocardiofacial syndrome) is primarily a T-cell deficiency,

Table 180.1 Treatment

Drug	Adult dose	Pediatric dose	Notes
Trimethoprim–sulfamethoxazole	15–20 mg/kg/d trimethoprim IV or PO in 4 divided doses for 21 d	As adult dose. Off-label use below 2 mo of age	Drug of choice. Risk of anemia, kernicterus in neonates under 28 d old
Pentamidine	4 mg/kg/day IV for 21 d	4 mo of age and older, as adult dose	
Dapsone	100 mg PO once daily, in combination with trimethoprim 15 mg/kg/d PO in 3 divided doses for 21 d	No pediatric data for treatment	
Atovaquone	1500 mg PO daily (or divided twice daily) for 21 d	Age >13 dose as adult Age 3–24 mo 45 mg/kg/d (max 1500 mg/d) in 2 divided doses PO for 21 days Other ages 30–40 mg/kg/d (max 1500 mg/d) in 2 divided doses	Take with food
Methylprednisolone	40 mg twice daily on days 1–5, 40 mg once a day on days 6–10, 20 mg once a day on days 11–21; begin as early as possible and within 72 h of PCP therapy	<12 yr 1 mg/kg every 6 h on days 1–7, 1 mg/kg twice daily on days 8–9, 0.5 mg/kg twice daily on days 10–11, 1 mg/kg once a day on days 12–16; begin as early as possible and within 72 h of PCP therapy	Best evidence in patients with moderate to severe HIV-related PCP

Table 180.2 Prophylaxis

Drug	Adult	Pediatric	Notes
Trimethoprim–sulfamethoxazole	One DS tab (160 mg trimethoprim) PO daily or 3 days a week (may be consecutively or every other day)	(2 months of age and older) 150 mg/m^2/d trimethoprim (max 320 mg/d) in 2 divided doses PO 3 times a week	Drug of choice
Pentamidine	300 mg by inhalation, monthly	5 yo and older, same as adult	May require specialized equipment and respiratory therapists to administer
Dapsone	100 mg PO daily or 200 mg PO weekly	(1 month of age and older) primary and secondary prophylaxis, 2 mg/kg PO once a day (max 100 mg/d); or 4 mg/kg PO once weekly (max 200 mg/dose)	
Pyrimethamine	50 mg PO once weekly PLUS leucovorin 25 mg PO once weekly PLUS dapsone 50 mg PO once daily OR 75 mg PO once weekly PLUS leucovorin 25 mg PO once weekly PLUS dapsone 200 mg PO once weekly		
Atovaquone	1500 mg PO daily	Age >13 dose as adult Age 3–24 mo 45 mg/kg PO daily (max 1500 mg/d) Other ages 30 mg/kg PO daily (max 1500 mg/d)	Take with food

and may result in CD4 counts similar to those seen in end-stage HIV infection, PCP has not been convincingly reported in patients with 22q11del. In these patients T-cell function is often intact and the CD4/CD8 ratio is preserved, whereas in HIV infection T-cell responses are blunted and the CD4/CD8 ratio is inverted. Nevertheless, some experts recommend PCP prophylaxis in individuals with 22q11del and very low CD4+ T-cell counts (under 500), especially if T-cell function has not yet been assessed or if any form of immune modulation or suppression is also present.

The use of steroids and other immunosuppressive agents is associated with varying levels of risk for PCP, and the indications for prophylaxis

are often dictated by the specific combination and duration of therapy, rather than the use of any one particular drug.

181. Miscellaneous fungi and algae

Cheryll N. Cash and George A. Pankey

Many nonendemic fungi and algae cause disease among the increasing populations of individuals at risk. These microorganisms, known as opportunistic agents, can cause disease if two major criteria are met: (1) the patient suffers from some predisposing factor that has mechanically or immunologically decreased the capacity to resist infection, and (2) the infecting agent can survive and multiply at body temperature. At present, more than 200 of these opportunists have been reported to cause infection.

Some opportunistic fungal infections are associated with predisposing factors such as ketoacidosis, neutropenia, or a defect in cell-mediated immunity. However, any trauma, disease state, or pharmacologic insult to the host's defenses increases the chance of fungal invasion, even from a patient's own resident flora.

The microorganisms considered here are ubiquitous but uncommon causes of disease in humans. Therefore, the diagnosis is usually made when a patient with an infectious disease does not respond to antibacterial therapy; when the microbiology laboratory isolates one of these agents; or when the pathologist identifies a fungus or algae in tissue, bronchoalveolar lavage, cerebrospinal fluid, etc. When a physician suspects a fungal pathogen, the laboratory should be informed and special requests made, for example, lysis centrifugation to maximize the yield from blood cultures or a specific fungal media to be inoculated.

Achlorophyllic unicellular algae produce spherical cells that multiply by cytoplasmic cleavage, forming a morula in tissue
Prototheca wickerhamii
Prototheca zopfii

DIAGNOSIS

Many of the pathogens considered require special media or conditions for culture. A culture is imperative for specific identification. The challenge is not isolating the agent once it is suspected, but rather determining the relevance of the isolate to the clinical picture. Mere isolation of an agent does not confirm pathogenesis. To prove causation, the culture must be associated with tissue invasion, as seen on biopsy or by repeated positive cultures of specific fungi from a usually sterile body fluid. The appearance of these agents in tissue is extremely variable and is typically broken down into hyalohyphomycoses, phaeohyphomycoses, opportunistic yeast, yeast-like fungi, and protothecosis (Table 181.1).

Virtually all of these species grow readily at 25°C to 30°C (77°F to 86°F). Most of these opportunistic fungi can be identified to genus in a clinical microbiology laboratory. However, a

Table 181.2 Therapy for infections by opportunistic fungi and algae

Pathogen	Characteristics	Diagnosis	Therapy
Hyalophyphomycoses – long septate hyphae in tissue			
***Fusarium* species**	Purpuric skin lesions with central necrosis, keratitis, pulmonary disease	Blood cultures: (50% positive) Histopathology: similar to *Aspergillus*	Reversal of neutropenia (G-CSF, GM-CSF) [a]LAmB + [b]Voriconazole (can switch to 200 mg q12h when stable)
Penicillium marneffei	Endemic in Southeast Asia, southern China, Taiwan, and Hong Kong Pulmonary disease, osteomyelitis, adenitis, skin lesions AIDS defining	Histopathology: from BAL Culture: easily from biopsy	[a]LAmB for 2 wk, followed by itraconazole (cs) 200 mg q12h for 12 wk Fluconazole not effective
Scedosporium prolificans ***S. apiospermum*** (***Pseudallescheria boydii***)	Normal host by traumatic implantation Mycetoma, meningitis, osteomyelitis, pneumonia (near drowning), sinusitis, endocarditis, spondylodiskitis, and keratitis	Histopathology: similar to *Aspergillus* and *Fusarium* Culture: from biopsy (correlate clinically) Molecular: cross-react with *Aspergillus* galactomannan	Surgical resection No optimal antifungal agent [b]Voriconazole (can switch to 200 mg q12h when stable) LAmB not effective
Phaeohyphomycoses (Dematiaceae) – pigmented environmental molds, irregular septated hyphae			
Exserohilum rostratum	Skin and subcutaneous tissue; sinusitis; occasional dissemination Local infection from skin and eye trauma in immunocompetent host Responsible for multistate meningitis and parameningeal outbreak from contaminated steroid injections	Molecular: fungal DNA by PCR (CDC) fungal culture (negative result does not rule out infection)	[a]LAmB for 6 wk, then oral voriconazole 200 mg q12h for 4 mo Dose modified to achieve serum trough levels of 2 to 5 μg/mL If CNS disease, use only voriconazole
Exophiala	Inhalation or traumatic implantation Subcutaneous nodules, keratitis, and/or skin abscess	Melanin in dematiaceous fungi with Fontana-Masson staining	Surgical excision Complete 12 wk of therapy with voriconazole 4 mg/kg IV or oral 200 mg (both every 12 h) or Posaconazole 200 mg orally every 6 h or Itraconazole (cs) 200 mg q12h ±LAmB for first 2 wk
Cladosporium	Distributed in air or as rotten organic material and contaminant on foods Causes keratitis, onychomycosis, and skin abscess Chromoblastomycosis	Cross-react with *Aspergillus* galactomannan	Surgical excision Complete 6 mo therapy with itraconazole (cs) 200 mg q12h or [b]Voriconazole (can switch to 200 mg orally every 12 h when stable)
Yeast or yeast-like fungi			
Pichia (***Hansenula***) ***P. anomala***	Catheter-related fungemia, prosthetic valve endocarditis NICU outbreaks		Remove intravascular catheter [a]LAmB if unresponsive: [b]Voriconazole or Itraconazole (cs) 200 mg twice daily + flucytosine 50–150 mg/kg/d divided into 4 doses
Rhodotorula "**red yeast**"	Contaminant of air, soil, lakes, and dairy products; colonizes plants and humans Fungemia, meningitis, peritonitis	Cross-react with *Aspergillus* latex agglutination test	Remove intravascular catheter [a]LAmB or Posaconazole 200 mg orally every 6 h

Table 181.2 *(continued)*

Pathogen	Characteristics	Diagnosis	Therapy
Saccharomyces cerevisiae	Colonizer of mucosal surfaces Pathogen in immune-compromised host Fungemia, prosthetic valve endocarditis, liver abscess, oral leukoplakia Associated with probiotic use		Removal of intravascular catheter [a]LAmB ± flucytosine 50–150 mg/kg/d divided into 4 doses Fluconazole and itraconazole resistant
Malassezia furfur	Fungemia associated with lipid infusion, folliculitis in AIDS, tinea versicolor Lipophilic fungus	KOH	Remove intravascular catheter; stop lipid IVs [b]Voriconazole for persistent fungemia Tinea versicolor: itraconazole (cs) 200 mg orally q12h, or topical selenium sulfide
Trichosporon beigelii	Fungemia, prosthetic valve endocarditis, chronic meningitis, peritonitis	Cross-reacts with cryptococcal latex agglutination	Correct neutropenia [a]LAmB [b]Voriconazole for LAmB-resistant strains
Protothecosis – Achlorophyllic algae, pervasive in nature, looks like a fungus microscopically. Only 2 species are known human pathogens in both immunocompetent and immunocompromised patients.			
Prototheca	Systemic infection, algaemia, peritonitis	Culture VITEK® 2	Remove intravascular catheter Excise isolated lesion [a]LAmB and/or [b]Voriconazole

Abbreviations: AIDS = acquired immunodeficiency syndrome; BAL = bronchial alveolar lavage; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte macrophage colony-stimulating factor; itraconazole (cs) = itraconazole cyclodextrin suspension (for better absorption); IV = intravenous; KOH = potassium hydroxide; PCR = polymerase chain reaction.

[a] LAmB = liposomal amphotericin B (5–10 mg/kg/d IV).

[b] Voriconazole (load 6 mg/kg IV every 12 hrs × 2 doses; maintenance 4 mg/kg IV every 12 hrs (maintain trough levels 2–5 μg/mL).

mycology expert is usually needed to identify the species. Fortunately, treatment of all species within a genus is frequently the same. Reliable intradermal or serologic tests are not available and direct microscopy using Gram stain, potassium hydroxide, India ink, and Papanicolaou preparations of lesion scrapings and sputum are often not helpful.

Species-specific PCR is presently available for pathogens such as *Aspergillus*. A lack of standardization has limited its acceptance as a diagnostic tool. PCR offers the possibility for broad-range identification while maintaining sensitivity. However, PCR does not establish pathogenicity of the identified organism.

THERAPY

Treatment of these infections can be challenging. Total excision, whenever feasible, should accompany any treatment regimen. There are no solid data on optimal drug therapy for many fungal infections because of the lack of controlled randomized trials. It is unlikely that anyone could ever collect enough cases to conduct double-blind therapeutic trials. At present, susceptibility testing can be performed for *Aspergillus, Candida*, and *Cryptococcus neoformans*, which most commonly produce disease in immunocompromised patients. Antifungal susceptibility testing is still in its infancy and variations in susceptibility occur with these organisms just as they do with bacteria. There are few data about in vitro correlation to in vivo results. When these fungi are isolated, they should be sent to a reference laboratory for susceptibility testing, including synergy studies.

Responses to antifungal drugs fail for multiple reasons: (1) the drug has no in vitro activity; (2) neutropenia was not reversed; (3) oral itraconazole or posaconazole was given while fasting or with antacids; (4) adequate blood levels were not obtained; (5) the dosage was too low or combination therapy was not used; (6) the drug is fungistatic rather than fungicidal; and (7) the drug is unable to concentrate in the area of concern, such as the brain. Voriconazole, itraconazole, and posaconazole trough levels must be monitored to ensure that therapeutic blood levels are achieved. Liposomal formulations of amphotericin B allow much higher dosages without increasing toxicity (Table 181.2). The echinocandins are

rarely active in vitro against these miscellaneous fungi and algae.

An infectious disease consultation should be obtained for all patients. Optimal therapies (Table 181.2) remain controversial at best. Surgical excision of localized skin and subcutaneous lesions is critical.

Major therapeutic approaches to treating fungal infections include correction of the neutropenia with colony-stimulating factors and decreased doses of immunosuppressant drugs. When immunosuppression cannot be corrected, prolonged antifungal therapy will be necessary, although morbidity and mortality will remain high.

PREVENTION

Immunocompromised patients should be educated on preventive measures regarding the risk of fungal infection from the environment. Prompt recognition of these pathogens in infected skin lesions after trauma is necessary for early therapy. Proper intravascular catheter care and neutropenia precautions and prevention are critical for hospitalized patients.

182. Cytomegalovirus

Rima I. El-Herte and Jeffery L. Meier

Cytomegalovirus (CMV) permanently resides in its human-restricted host by toggling between productive and latent states of infection. CMV infection is serologically marked by immunoglobulin (Ig) G antibody against CMV. CMV seroprevalence varies widely by geographic region, ranging from 45% to 100% for women of reproductive age. In the US population, CMV seroprevalence is 50% overall and varies by age, socioeconomic status, sexual activity/practice, and race/ethnicity. Over 90% of all persons are CMV seropositive by age 80, 55% of women are seropositive by age 30, and the annual CMV seroconversion (primary infection) rate is ~2% for women of reproductive age. Congenital CMV infection afflicts ~1% of all babies born in the United States, is the leading infectious cause of birth defects, and the most common non-genetic cause of sensorineural hearing loss.

CMV is transmitted through close mucosal contact with body fluids bearing infectious CMV particles, i.e., saliva, urine, breast milk, semen, and cervical secretions. Infants and young children experiencing a primary (acute) CMV infection often continue to shed CMV in urine and, sometimes, saliva for several weeks to months. Immunosuppression or underlying illness may bring about viral shedding in body fluids at any stage of the infection. CMV persists in virtually all tissues and resides latently in monocytes, dendritic cells, and myeloid precursors. Viable tissue or leukocytes of CMV-seropositive donors are a source of CMV infection in seronegative persons. Risk for intrauterine CMV transmission is greatest for maternal primary CMV infection and less for reinfection with another CMV strain or CMV reactivation.

In immune-competent persons, the primary CMV infection is typically unapparent clinically. Occasionally, it causes self-limiting illness presenting as a heterophile-negative mononucleosis, nonspecific viral syndrome, or febrile hepatitis. Protracted illness or tissue-invasive disease rarely ensues. A primary infection occurring in the first trimester of pregnancy carries the greatest risk for severe CMV disease in the fetus. Maternal infection in the third trimester of pregnancy carries greatest risk for intrauterine infection but lower risk of neonatal disease.

Acquired immunodeficiency syndrome (AIDS), hematopoietic stem cell transplantation (HSCT), solid organ transplantation (SOT), and potent immunosuppressive therapies are conditions that profoundly impair cellular immunity and, thereby, predispose to life-threatening or debilitating CMV disease resulting from primary, reactivation, or recurrent CMV infection. CMV produces a wide spectrum of disease that can involve any organ. Leading clinical manifestations of CMV-related disease vary among the different types of immunocompromised patient populations. Tissue-invasive CMV disease commonly presents as retinitis, gastrointestinal disease, hepatitis, pneumonitis, and encephalitis. CMV is indirectly linked to allograft dysfunction, superinfection, post-transplant lymphoproliferative disorder, and reduced survival of human immunodeficiency virus (HIV)-positive persons.

DIAGNOSIS

In the immunocompromised person, CMV serology is unreliable in diagnosing active CMV infection. Determination of CMV IgG status of the pretransplant donor and recipient informs post-transplant CMV infection risk and management. A primary CMV infection in an acutely ill but otherwise healthy person is suggested by serologic evidence of IgM antibody to CMV antigen. Unfortunately, CMV IgM finding is often falsely positive and does not discriminate between CMV IgM produced following primary infection, reactivation, or reinfection. A highly elevated CMV IgM level increases the probability that primary CMV infection is the cause of the acute illness. Presence of low-avidity CMV IgG index

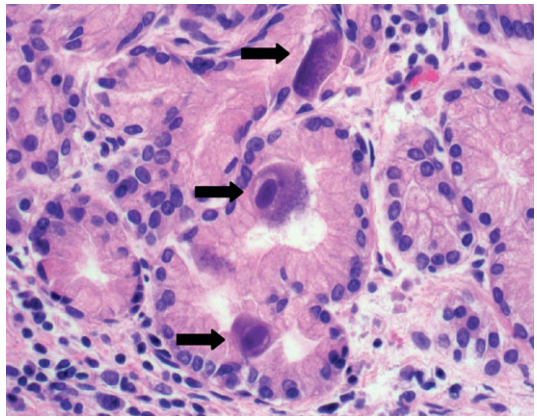

Figure 182.1 Cytomegalic inclusion disease. Arrows point to characteristic CMV-infected cells, which are large and contain intranuclear and ground-glass cytoplasmic inclusions. H&E staining.

confirms the diagnosis of primary CMV infection (avidity measures maturity of IgG, so that low avidity suggests recent infection). CMV IgG seroconversion between acute and convalescence periods of primary infection is uncommon, because CMV IgG is produced in substantial amounts during acute illness. A confirmed primary CMV infection during pregnancy (CMV IgM positivity and low-avidity IgG index) warrants expert consultation to evaluate possible congenital infection. This typically entails fetal ultrasound and consideration of amniocentesis for detection of CMV DNA by polymerase chain reaction (PCR).

Tissue-invasive CMV disease is defined by presence of active CMV infection in the tissue of patients with clinical findings attributed to the infection. Not all patients with active CMV infection have clinically significant disease. Cytomegalic cells with distinctive intranuclear and intracytoplasmic inclusions (Figure 182.1) are hallmarks of active CMV infection. Detection of CMV in tissue by culture, immunohistochemical analysis (CMV antigen), or *in situ* hybridization (CMV nucleic acid) also indicates active CMV infection, but requires clinical and histopathologic correlations to make the CMV disease diagnosis. Ophthalmologists typically diagnose CMV retinitis based on fundoscopic findings of distinctive retinal changes with perivascular infiltrate, atrophy, and hemorrhage. In transplant recipients, the CMV syndrome is characterized by a constellation of clinical (fever or malaise) and laboratory (leukopenia and thrombocytopenia) abnormalities plus evidence of CMV in blood, as detected by culture, antigen test, or nucleic acid assay. Probable CMV disease in transplant recipients is defined as clinical illness and organ dysfunction likely attributed to CMV in blood, bronchoalveolar lavage fluid (BALF), or cerebrospinal fluid (CSF). In AIDS, the diagnoses of CMV encephalitis, polyradiculopathy, and myelitis are supported by detection of CMV DNA in CSF.

Quantification of CMV DNA by PCR predicts or assesses CMV disease and prognosis. Having a measurable amount of CMV DNA in blood, CSF, BALF, vitreous fluid, or amniotic fluid is evidence of CMV replication. Latent CMV DNA levels in these fluids are below the lower limit of detection reported in clinical assays. In HSCT and SOT recipients, the level of CMV DNA in blood (DNAemia) guides use of anti-CMV therapy for pre-empting or treating CMV disease. While this test is useful in assessing response to anti-CMV therapy in transplant patients, the monitoring of CMV DNAemia has poor positive predictive value for progression or relapse of AIDS-associated retinitis. The COBAS AmpliPrep/COBAS TaqMan CMV test (Roche Molecular Diagnostics) is the first US Food and Drug Administration (FDA)-approved assay that uses the World Health Organization (WHO) International Standard to quantify CMV DNA load in plasma. Importantly, CMV DNAemia might also be absent during tissue-invasive CMV disease. In AIDS-associated CMV retinitis, for example, CMV DNAemia is often absent. Risk of sequelae in congenitally infected newborns correlates with level of CMV DNAemia in the neonates. Detection of CMV DNA in amniotic fluid indicates congenital CMV infection.

Measurement of CMV pp65 antigen in blood leukocytes is an alternative approach for detecting and semi-quantifying level of active CMV infection, though it is less sensitive than nucleic acid amplification and is reduced by neutropenia. Assessment of CMV-specific T-cell response (i.e., interferon-γ [IFN-γ] release in response to CMV antigen) for predicting CMV reactivation and disease may have clinical utility in the transplant population.

THERAPY

The FDA approved use of ganciclovir, valganciclovir, cidofovir, and foscarnet for specific CMV treatment indications. Table 182.1 summarizes the recommended dosing schedules for these agents and of their use in clinical practice.

Table 182.1 Preventive and treatment regimens for CMV

Agent	Indications	Dosing regimen	Toxicities	Monitoring	Comments
Intravenous					
Ganciclovir	Treatment of visceral or disseminated disease Prophylaxis or pre-emptive therapy in transplant recipients	Induction: 5 mg/kg q12h × 14–21 d Maintenance: 5 mg/kg qd (modify dose in renal failure) 5 mg/kg qd or BID (modify dose in renal failure)	Catheter-related complications, neutropenia, thrombocytopenia, renal failure	Induction: CBC 2×/wk, Cr weekly Maintenance: CBC qwk, Cr q1–3wk	If ANC 500–750, consider SQ G-CSF If ANC ≤500 or platelets ≤25 K, hold ganciclovir Increased toxicity of zidovudine or imipenem; increased level of didanosine Causes infertility, teratogenicity, and embryotoxicity in animals
Foscarnet	Treatment of visceral or disseminated disease	Induction: 90 mg/kg q12h (or 60 mg/kg q8h) × 14–21 d Maintenance: 90–120 mg/kg qd (modify dose in renal failure) Maximum dose is 120 mg/kg qd	Catheter-related complications, nephrotoxicity, paresthesias, cation chelation, genital ulcerations, nausea, marrow suppression	Induction: CBC, Cr, cations (K^+, Mg^{2+}, Ca^{2+}), and phosphate 2–3× qwk Maintenance: Cr, cations, and phosphate qwk, CBC q2wk	If Cr >2.8, hold foscarnet until Cr ≤2.1 mg/dL Adjust dosage for reduced renal function Hydration reduces renal toxicity Caution if seizures
Cidofovir	Treatment of retinitis (limited experience with use for salvage therapy for CMV disease in other viscera)	Induction: 5 mg/kg/wk × 2; infuse over 1 h Maintenance: 5 mg/kg q2wk; infuse over 1 h (reduce dose to 3 mg/kg if Cr increase 0.3 mg/dL)	Nephrotoxicity with Fanconi syndrome, neutropenia, uveitis, ocular hypotony, probenecid rash Probenecid contraindicated in persons with severe sulfa allergy	Induction: Cr and UA every dose Maintenance: Same plus intraocular pressure qmo	1–2 L saline hydration, with 1 L given before cidofovir infusion; probenecid, given 3 h before (2 g), at 3 h (1 g) and 8 h (1 g) after cidofovir infusion Caution if diabetes mellitus Do not use if Cr >1.5 mg/dL CrCl ≤55 mL/min, ≥100 mg/dL proteinuria, or receiving other nephrotoxic agents
Intraocular					
Ganciclovir implant	Treatment of retinitis	Surgical: Intraocular implantation via pars plana of (4.5 mg) implant; replacement q6–8mo Concomitant systemic therapy: see oral valganciclovir maintenance	Transient blurred vision, retinal detachment, hemorrhage, infection	Ophthalmologic follow-up	Requires addition of systemic therapy to reduce CMV disease risk in contralateral eye and other organs Implant releases 1 μg/h of ganciclovir Contraindicated if there is external eye infection and thrombocytopenia
Ganciclovir intravitreal injection	Treatment of retinitis	Induction: 200 μg to 2 mg in 0.1 mL twice per week for 2–3 wk Maintenance: once weekly	Less systemic side effects; procedural-related complications such as retinal detachment, vitreous hemorrhage, endophthalmitis, and cataract	Ophthalmologic follow-up	Requires addition of systemic therapy to reduce CMV disease risk in contralateral eye and other organs Contraindicated in external eye infection and thrombocytopenia
Foscarnet intravitreal injection	Treatment of retinitis	2.4 mg in 0.1 mL twice per week for 2–3 wk	Less systemic side effects; procedural-related complications such as retinal detachment, vitreous	Ophthalmologic follow-up	Requires addition of systemic therapy to reduce CMV disease risk in contralateral eye and other organs

Table 182.1 *(continued)*

Agent	Indications	Dosing regimen	Toxicities	Monitoring	Comments
			hemorrhage, endophthalmitis, and cataract		Contraindicated in external eye infection and thrombocytopenia
Oral					
Valganciclovir	Treatment of visceral or disseminated disease Prophylaxis or pre-emptive therapy in transplant	Induction: 900 mg BID × 14–21 d Maintenance: 900 mg qd (modify dose in renal failure 900 mg qd or BID, with food (modify dose in renal failure)	Neutropenia, thrombocytopenia	Induction: CBC 2×/wk, Cr weekly Maintenance: CBC qwk, Cr q1–3wk	If ANC 500–750, consider SQ G-CSF If ANC ≤500 or platelets ≤25 K, if Hg <8 mg/dL consider holding dose Increased toxicity of zidovudine or imipenem; increased level of didanosine Causes infertility, teratogenicity, and embryotoxicity in animals
Valacyclovir	Prophylaxis in solid organ transplant recipients	2 g QID (modify dose in renal failure)	Hallucinations, confusion, Marrow toxicity	CBC and Cr q2wk	Less effective than ganciclovir; therefore, use limited to low-risk patients
CMV hyperimmunoglobulin					
CMV immunoglobulin intravenous (CytoGam) (*Cytotect Biotest, Megalotect in Europe)	Treatment of CMV pneumonitis in bone marrow transplant recipient Prophylaxis in solid organ transplant recipients *Prevention of congenital CMV infection *Treatment of congenital CMV infection	400 mg/kg days 1, 2, and 7 200 mg/kg day 14 plus IV ganciclovir (see IV ganciclovir) 50–150 mg/kg q2–4wk (various dosing regimens have been used) *100 mg/kg (100 U/kg) q 4 weeks until delivery *200 mg/kg (200 U/kg) q4wk until delivery	Fever, myalgia, arthralgia, nausea, wheezing, hypotension, aseptic meningitis	Vital signs before, during, and after infusion	Derived from pooled adult human plasma Increase infusion rate as tolerated, 15–60 mg/kg/h Caution if IgA deficiency *Used in Europe in pregnancy In USA, off-label use of CMV immune globulin in pregnancy is controversial

Abbreviations: SQ = subcutaneous injection; CBC = complete blood count; Cr = serum creatinine; ANC = absolute neutrophil count; CMV = cytomegalovirus; UA = urine analysis; G-CSF = granulocyte colony-stimulating factor

Fomivirsen, a therapeutic agent administered by intraocular injection, is an FDA-approved agent that is no longer manufactured, and oral ganciclovir is not available in the United States. Investigational anti-CMV drugs (e.g., cyclopropavir, brincidofovir, and letermovir) are in clinical development.

AIDS

CMV end-organ disease in AIDS mostly involves persons with CD4+ T-lymphocyte counts ≤50 cells/mm^3. CMV retinitis accounts for 85% of all AIDS-associated CMV disease. Treatment of CMV retinitis is selected from options of oral valganciclovir alone or with intravitreal injection of foscarnet or ganciclovir, or intravenous (IV) ganciclovir, foscarnet, or cidofovir. The treatment approach is selected based on individual patient characteristics (ability to absorb oral medication, adhere to treatment, achieve immune recovery, etc.) and extent/location of the retinal lesion. Systemic anti-CMV therapy is needed to prevent CMV disease from developing in the contralateral eye and other organs. The ganciclovir intraocular implant is no longer manufactured. Intravitreal foscarnet or ganciclovir may be used in this situation. Concomitant antiretroviral therapy (ART) is key for recovering immune control of CMV. CMV retinitis is treated for 14 to 21 days at induction

therapy dosing. Maintenance therapy (secondary prophylaxis) is continued for at least 3 to 6 months after CD4+ T-lymphocyte count >100 cells/mm^3 and CMV retinitis is quiescent. Secondary prophylaxis is resumed when the CD4+ T-lymphocyte count falls below 100 cells/mm^3. Immune restoration uveitis may develop as an ART-induced inflammatory response to CMV that is managed with periocular or oral corticosteroids. An early first relapse (≤3 months) of CMV retinitis will often respond to reinstituting the same initial treatment regimen. Prolonged use of ganciclovir or valganciclovir is associated with the emergence of ganciclovir-resistant CMV. Subsequent therapy is guided by DNA sequencing-based determination of antiviral resistance mutations in the CMV phosphotransferase (UL97) and polymerase (UL54) genes produced from PCR-amplified specimens produced. Low-level ganciclovir-resistant CMV resulting from viral phosphotransferase mutations may still respond to intravitreal injection of ganciclovir or the ganciclovir intraocular implant. A CMV with high-level ganciclovir resistance resulting from mutations in both viral phosphotransferase and polymerase requires treatment with a different class of anti-CMV drug. The polymerase mutations often confer cross-resistance to cidofovir and, less frequently, confer cross-resistance to foscarnet.

AIDS-associated CMV esophagitis and colitis are treated initially with IV ganciclovir (or IV foscarnet). Oral valganciclovir is an option if absorption is not a concern. Treatment duration is 21 to 28 days or until the disease resolves. Secondary prophylaxis is not always needed. CMV pneumonitis is treated with IV ganciclovir, oral valganciclovir, or IV foscarnet. CMV neurologic disease may initially require double therapy with IV ganciclovir and IV foscarnet; both agents fall short in achieving target drug levels in CSF. Cidofovir is less effective than ganciclovir or foscarnet in reducing AIDS-related CMV DNAemia.

Transplantation

Use of either antiviral prophylaxis (chemoprophylaxis) or pre-emptive therapy in the first 3 to 6 months after transplant is an effective strategy for preventing CMV disease in HSCT and SOT recipients. In chemoprophylaxis, an anti-CMV drug is given to all patients in a specific population to suppress CMV replication. Pre-emptive therapy limits anti-CMV drug use to patients who develop asymptomatic CMV replication that is discovered through successive testing to exceed a threshold level of CMV DNAemia or antigenemia. The viral load threshold used for initiating pre-emptive therapy varies by the assay used, transplant type, degree of immunosuppression, and other factors that influence risk of CMV disease. In the highest-risk patients, chemoprophylaxis may have advantages over pre-emptive therapy. SOT patients at highest risk for CMV disease are CMV-negative recipients of CMV-positive organs (D+/R−) and recipients of donor lung, heart, or intestine.

Oral valganciclovir or IV ganciclovir is used for chemoprophylaxis. Pre-emptive therapy is initiated with full-treatment doses of oral valganciclovir or IV ganciclovir for at least 2 weeks (induction phase), followed by suppressive therapy (maintenance phase). Foscarnet is reserved for patients who are intolerant to or failing ganciclovir or valganciclovir. High-dose acyclovir or valacyclovir is less effective than ganciclovir for chemoprophylaxis, but is sometimes used in low-risk renal transplant recipients. Late-onset CMV disease in HSCT and SOT recipients is more likely to occur in patients having graft-versus-host disease or received chemoprophylaxis. CMV replication during or after lengthy exposure to ganciclovir or valganciclovir increases probability of CMV having developed resistance to ganciclovir. Insufficient dosing of valganciclovir or IV ganciclovir favors development of ganciclovir-resistant CMV.

CMV disease in HSCT and SOT recipients is treated with IV ganciclovir or oral valganciclovir. Ganciclovir IV is preferred in children, in patients having life-threatening CMV disease, and when absorption of valganciclovir may be suboptimal. A commonly used schedule for induction therapy is 14 to 28 days, often followed by maintenance (secondary prophylaxis) therapy. Immune suppression should be decreased if possible. Genotypic antiviral resistance testing should be performed if drug resistance is suspected. A CMV with minor mutations in the phosphotransferase gene (UL97) may respond to treatment with higher doses of IV ganciclovir. A CMV with major mutations in this gene should be treated with IV foscarnet. Viral polymerase gene (UL54) mutations conferring resistance to ganciclovir are likely to confer cross-resistance to cidofovir. Most ganciclovir-resistant CMV strains are susceptible to foscarnet. Cidofovir IV is considered a therapy of last resort because efficacy data in SOT are lacking, results in HSCT are mixed, and risk of nephrotoxicity is high. The combination of IV ganciclovir and CMV hyperimmune globulin is

used for CMV pneumonia in HSCT recipients. Monitoring of CMV DNAemia or pp65 antigenemia levels gauges treatment response and informs decision on treatment duration.

Congenital infection

Screening of pregnant women for CMV is not standard of care in the United States, because there is no proven therapy for congenital CMV infection in utero. A nonrandomized study of CMV IV hyperimmune globulin given during pregnancy for acute fetal CMV infection suggests efficacy, but a small randomized trial did not demonstrate protection. Ganciclovir is classified as pregnancy category C and is teratogenic in small animals. Six weeks of IV ganciclovir therapy started in neonates with symptomatic congenital CMV infection appears to decrease risk for hearing impairment, but dose-limiting bone marrow toxicity is common.

The otherwise normal host

Symptomatic CMV illness in otherwise healthy persons (e.g., heterophile-negative mononucleosis, viral syndrome, or hepatitis) is usually self-limiting. Use of oral valganciclovir or IV ganciclovir is reserved for debilitating protracted illness or tissue-invasive disease.

ANTIVIRAL AGENTS

Ganciclovir and valganciclovir

Ganciclovir is a guanosine analog. The intracellular half-life of the active metabolite is 16.5 hours. Ganciclovir concentration in vitreous fluid and CSF is somewhat lower and more variable than in serum. Orally administered valganciclovir, a prodrug of ganciclovir, attains levels similar to that of IV ganciclovir at standard treatment dose. Ganciclovir also has activity against herpes simplex virus 1 (HSV-1), HSV-2, varicella-zoster virus (VZV), Epstein–Barr virus (EBV), human herpesvirus 6 (HHV-6), HHV-7, and herpes B virus.

The kidneys eliminate ganciclovir metabolites, requiring adjustment of ganciclovir dose according to creatinine clearance. Granulocytopenia is a common adverse effect that can be managed with colony-stimulating factor and avoidance of other marrow-suppressive agents. Thrombocytopenia, anemia, central nervous system toxicity (e.g., headache, seizures, and confusion), and renal failure may also be observed. Ganciclovir caused infertility, teratogenicity, and embryotoxicity in animal studies. The IV route of administration risks catheter-related infection, whereas the intraocular implant risks endophthalmitis, hemorrhage, and other retinal-vitreous problems.

Foscarnet

Foscarnet (phosphonoformic acid) directly inhibits viral DNA polymerase activity. It is cleared by the kidneys, so dosage adjustment according to creatinine clearance is required. The major toxicity is renal impairment, which may be reduced by hydration. Mineral and electrolyte abnormalities, such as hypocalcemia, hyperphosphatemia, hypophosphatemia, hypokalemia, and hypomagnesemia, are common. Although manageable, these abnormalities can precipitate seizures. Chelation of ionized calcium by foscarnet may result in numbness, tingling, and paresthesias, and can be prevented by slowing the infusion rate. Other notable adverse events include anemia, granulocytopenia, genital ulcers, and catheter-related sepsis. Foscarnet should not be used in persons receiving amphotericin B, aminoglycosides, or other nephrotoxic agents.

Cidofovir

This active metabolite inhibits the viral DNA polymerase, terminates viral DNA chain elongation, and has an intracellular half-life of 17 to 65 hours. Cidofovir is nephrotoxic and contraindicated in persons with renal insufficiency (Cr >1.5 mg/dL, CrCl ≤ 55 mL/min, or $\geq 2+$ proteinuria) or receiving other nephrotoxic agents. Nephrotoxicity is minimized by IV prehydration and administration of probenecid. Probenecid is contraindicated in persons with history of a severe sulfa allergy. Neutropenia, ocular hypotony, and metabolic acidosis (Fanconi syndrome) are other potential toxicities of the drug. Cidofovir is gonadotoxic, embryotoxic, and carcinogenic in animals.

Cytomegalovirus hyperimmune globulin

CMV hyperimmune globulin IV (CMVIG) is pooled human IgG enriched 4- to 8-fold in anti-CMV antibody titer compared with standard preparations of IV immunoglobulin. CMVIG is used at some centers for passive immunoprophylaxis to prevent or attenuate CMV disease in

high-risk (D+/R−) lung, heart, and intestine transplant populations. CMVIG is combined with IV ganciclovir for treatment of CMV pneumonitis in HSCT recipients. The use of CMVIG to prevent and treat congenital CMV infection is the subject of ongoing investigations.

PRIMARY PREVENTION

Primary prevention strategies target CMV-seronegative persons at risk of serious CMV disease. Vaccines are under development. Transmission of CMV by transfusion is prevented by administration of CMV-seronegative or leukocyte-depleted blood products. Use of condoms is thought to prevent sexual transmission of the virus. Attention to hand hygiene is advised to prevent CMV transmission from changing diapers and wiping oral secretions of toddlers who may be shedding the virus. Avoidance of contact with saliva when kissing a child may also reduce transmission risk.

183. Dengue

Nguyen Thanh Hung

Dengue is caused by any of four closely related viruses, or serotypes (dengue 1–4). Dengue viruses are small single-stranded RNA viruses, and belong to the genus *Flavivirus*, family Flaviviridae. Dengue is transmitted between people by the mosquitoes *Aedes aegypti* and *Aedes albopictus*, which are found throughout the world. In the last 50 years, there has been a dramatic increase in the global incidence of dengue virus infections with an estimated 50 million infections occurring annually in at least 100 countries in Asia, the Pacific, the Americas, Africa, and the Caribbean. Dengue virus infections may cause symptomatic infections or asymptomatic seroconversion. Symptomatic dengue infection has a wide range of clinical presentations which includes severe and nonsevere manifestations. While most patients recover following a self-limiting nonsevere clinical course, a small proportion progress to severe disease, mostly characterized by plasma leakage with or without hemorrhage.

CLINICAL MANIFESTATIONS

After an incubation period of 3 to 7 days, the illness begins abruptly and is followed by three phases – a febrile phase, a critical phase, and a recovery phase.

Febrile phase

The febrile phase is characterized by high temperature (≥38.5°C) accompanied by headache, vomiting, myalgia, joint pain, and a transient macular rash. High fever may cause neurologic disturbances and febrile seizures in young children. Hemorrhagic manifestations include a positive tourniquet test, easy bruising and bleeding at venipuncture sites, fine petechiae, epistaxis, gingival bleeding, and mild gastrointestinal bleeding (Figure 183.1, Panel A, B, and C). A palpable liver may be noted, especially in young infants and children. The full blood count examination reveals leukopenia, mild-to-moderate thrombocytopenia, and normal hematocrit value. This acute febrile phase usually lasts 2 to 7 days, and most patients recover spontaneously after this phase.

Critical phase

During the transition from the febrile to afebrile phase, patients without an increase in capillary permeability will improve uneventfully. In a small proportion of patients, systemic vascular leak syndrome becomes apparent, evidenced by increasing hemoconcentration, pleural effusions, and ascites (Figure 183.2). The degree of increase above the baseline haematocrit often reflects the severity of plasma leakage. In less severe cases, these changes are minimal and transient, reflecting a mild degree of plasma leakage, and patients will recover spontaneously. In more severe cases, when plasma loss is critical, shock ensues. Shock (dengue shock syndrome) is often preceded by warning signs. The warning signs of impending deterioration include abdominal pain or tenderness; persistent vomiting; mucosal bleeding; lethargy, restlessness; tender hepatomegaly; and an increase in hematocrit concurrent with a rapid decrease in platelet count. The patient in shock may die within 12 to 24 hours if appropriate treatment is not promptly administered, or recover rapidly following proper intravenous fluid therapy. Uncorrected shock can lead to severe complications with development of multiple organ dysfunctions, respiratory failure, metabolic acidosis, severe gastrointestinal bleeding, and a poor prognosis.

Hemorrhagic manifestations are most common during this critical period. In children, significant bleeding is usually associated with profound and prolonged shock. However, major skin bleeding and/or mucosal bleeding may occur in adults with only minor plasma leakage (Figure 183.1, Panel C). Moderate-to-severe thrombocytopenia, transient increase in the

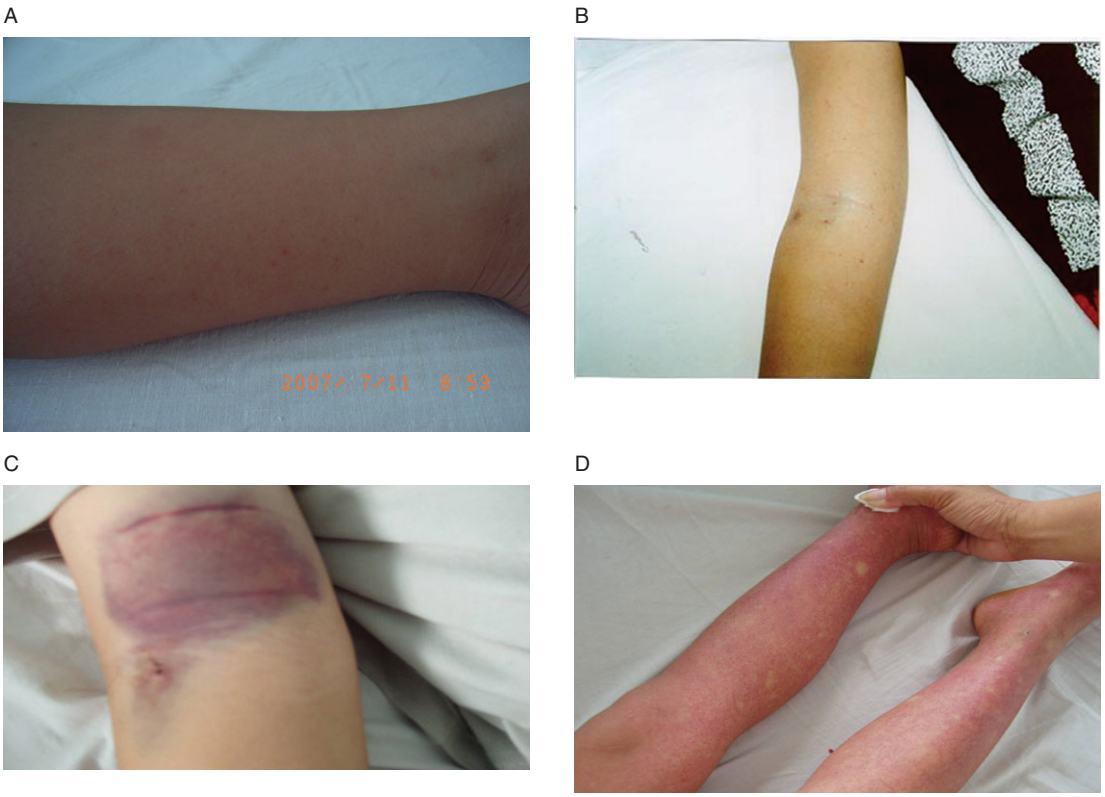

Figure 183.1. Hemorrhagic manifestations in dengue patients.
Panel A illustrates a petechial rash in a child with dengue. Panel B illustrates minor bleeding around injection sites. Panel C illustrates a hematoma in a patient with severe dengue. Panel D illustrates a characteristic confluent petechial rash in the recovery phase.

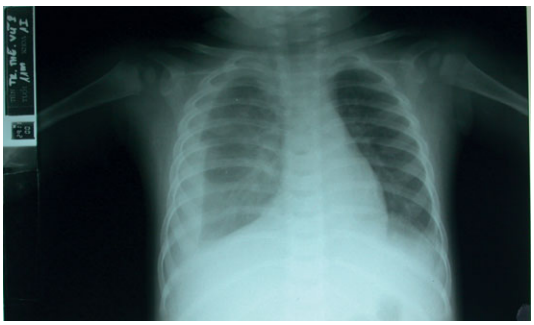

Figure 183.2. Systemic vascular leak syndrome evidenced by pleural effusion in an infant dengue patient.

activated partial-thromboplastin time, and a decrease in fibrinogen levels are frequently noted. Severe organ impairment such as severe hepatitis, encephalitis, or myocarditis and/or severe bleeding may infrequently occur without obvious plasma leakage or shock.

Convalescent phase

Most dengue patients will recover rapidly and uneventfully within 24-48 hours after shock has been reversed. Indicators of recovery include improved general condition, stable vital signs, and the return of appetite, diuresis and sinus bradycardia. Some patients develop a characteristic confluent petechial rash with small round areas of normal skin on their lower extremities (Figure 183.1, Panel D). Some patients have signs of fluid overload (respiratory distress, pulmonary edema, or heart failure associated with gross peripheral edema, large pleural effusions, and ascites) due to excessive intravenous therapy and reabsorption of extravasated plasma from the interstitial compartment.

DIAGNOSIS

Clinicians should suspect dengue in persons who live in or travel to a dengue-endemic area (South-East Asia, the Americas, the Western Pacific, and

the Eastern Mediterranean) with acute febrile syndromes associated with two of these signs/symptoms: nausea, vomiting; rash; aches and pains; tourniquet test positive; leukopenia; and any warning sign as mentioned above. Laboratory diagnosis of dengue is made by detecting the virus and/or any of its components such as virus genome and dengue antigen or by investigating the serologic responses present after infection. Clinicians should keep in mind that laboratory diagnosis is usually not necessary for clinical management except in atypical cases or when constructing a differential diagnosis. A diagnosis of dengue infection is confirmed by the detection of the virus, the viral genome, or nonstructural protein 1 (NS1) antigen in the acute sera which are collected during the febrile phase, or seroconversion of IgM/IgG from negative to positive or a 4-fold increase in antibody titer in paired sera. A positive IgM serology or a hemagglutinin inhibition test (HIA) antibody titer of 1280 or higher are considered a probable dengue infection. Both probable and confirmed dengue cases should be notified to health authorities.

DENGUE CASE CLASSIFICATION

Patients were previously classified as having either dengue fever or dengue hemorrhagic fever. Dengue hemorrhagic fever was further classified into four severity grades, with grades III and IV being defined as dengue shock syndrome. There have been many reports of difficulties in the use of this classification. With the recent revision of the World Health Organization dengue classification scheme, patients are now classified as having either dengue or severe dengue. Patients who recover without major complications are classified as having dengue, whereas those who have any of the following conditions are classified as having severe dengue: severe plasma leakage leading to shock (dengue shock syndrome), accumulation of serosal fluid sufficient to cause respiratory distress; severe bleeding; and severe organ impairment.

DIFFERENTIAL DIAGNOSIS OF DENGUE

Early in the febrile phase, the differential diagnosis of dengue includes other arboviral infections, measles, rubella, enterovirus infections, adenovirus infections, and influenza. Depending on local frequency and epidemiologic characteristics of febrile diseases, other diseases such as typhoid, malaria, leptospirosis, viral hepatitis, rickettsial diseases, bacterial sepsis, and meningococcal disease should be considered as part of the differential diagnosis. Clinicians should also remember that some dengue patients with liver enlargement and severe abdominal pain may mimic surgical conditions such as acute appendicitis and hepatic abscess. Misdiagnosing and performing unnecessary surgery will pose these dengue patients at risk of severe hemorrhage.

MANAGEMENT

Treatment is supportive with special emphasis on careful fluid management. Patients without complications can be managed as outpatients and followed closely every day from day 3 of their illness, until they have been afebrile for more than 48 hours without the use of antipyretics. Practically the hematocrit and platelet count should be determined at the first visit, and then checked once to twice daily. Oral rehydration should be encouraged with oral rehydration solution (ORS), fruit juice, and other fluids containing electrolytes and sugar. Give acetaminophen/paracetamol for high fever if the patient is uncomfortable. Do not give acetylsalicylic acid (aspirin), ibuprofen, or other nonsteroidal anti-inflammatory agents (NSAIDs) because of the risks of gastritis or bleeding. Instruct the patients or caregivers to return to the nearest hospital immediately if the patients have any of the warning signs.

For the patients with warning signs, judicious volume replacement of lost plasma by intravenous fluid therapy with isotonic crystalloid solutions from this early stage may modify the course and the severity of disease. Parenteral fluid therapy is only required for 24 to 48 hours in most patients since the capillary leak resolves spontaneously after this time.

Patients with dengue shock syndrome need emergency treatment with fluid resuscitation. The recommended regimen for the treatment of dengue shock patients is as follows: immediate and rapid replacement of the plasma loss with isotonic crystalloid solutions or, in the case of profound shock, colloid solutions; continued replacement of further plasma losses to maintain effective circulation for 24 to 48 hours; correction of metabolic and electrolyte disturbances; and blood transfusion – in patients with severe bleeding. Platelet concentrates, fresh frozen plasma, and cryoprecipitate may also be used in cases of severe bleeding. Dengue shock patients should be under close observation around the clock, until it is certain that danger has passed. Generally, the duration of intravenous therapy should not

exceed 24 to 48 hours after the patient is out of shock. Electrolyte levels and blood gases should be determined periodically in severe cases. In patients with severe and complicated dengue, mechanical ventilation, vasopressor and inotropic therapies, renal-replacement therapy, and other treatment of organ impairment may be required.

PREVENTION

Effective vaccines against dengue and specific medications to treat a dengue infection are not yet available. Dengue is transmitted between people by the mosquitoes *A. aegypti* and *A. albopictus*, so the best measure to prevent dengue is to reduce mosquitoes and avoid mosquito bites. Eliminating the places where the mosquito lays her eggs, such as artificial containers that hold water in and around the home, and cleansing water containers, help reduce mosquitoes. The adult mosquitoes like to bite indoors during the day and at night when the lights are on. Travelers in dengue-endemic areas should avoid mosquitoes during the day by using insect repellents and sleeping under a mosquito bed net or using air-conditioning. Current research is exploring new antiviral or other therapeutic drugs as well as innovative approaches to preventing transmission.

184. Enteroviruses

Michael N. Oxman

Enteroviruses (EVs), so named because most members infect the alimentary tract and are shed in the feces, cause a variety of diseases in humans and lower animals. They constitute one of the six major subgroups, or genera, of the family Picornaviridae [*pico*, "small"; *rna*, "ribonucleic acid"]. The other genera of Picornaviridae are the *Rhinovirus*, *Cardiovirus*, *Aphthovirus*, and two newly designated genera, *Hepatovirus*, the prototypic member of which is human hepatitis A virus; and *Parechovirus*, which contains two serotypes that were previously classified as echoviruses types 22 and 23, and at least 14 additional serotypes.

PHYSICAL AND BIOCHEMICAL PROPERTIES

EVs, like all members of the picornavirus family, are small, nonenveloped, spherical (icosahedral) viruses approximately 30 nm in diameter. Their capsids consist of 60 structural subunits, each composed of 4 unique polypeptides: VP1, VP2, VP3, and VP4. Their genome consists of a linear, single-stranded, unsegmented molecule of RNA (of approximately 7500 nucleotides) that has the same polarity as messenger RNA.

EVs are stable over a wide range of pH (pH 3 to 10), permitting them to retain infectivity during passage through the gastrointestinal tract. They are not inactivated by ether, alcohol, or other lipid solvents, but are readily inactivated by formaldehyde or phenol. EVs retain infectivity for days at room temperature, weeks at refrigerator temperature, and indefinitely when frozen at −20°C or lower. Molar $MgCl_2$ further increases their thermostability, facilitating the use of oral polio vaccines in tropical areas where availability of refrigeration is limited.

CLASSIFICATION OF ENTEROVIRUSES

Historically, human EVs have been sub-classified into polioviruses, group A and group B Coxsackieviruses, and echoviruses on the basis of antigenic relationships, differences in host range, and types of disease produced (Table 184.1). By 1969, 67 species (serotypes) of human EV had been identified and classified according to these criteria, although reclassification and redundancy have reduced this number from 67 to 61. New EVs discovered since 1970 have been assigned to the EV species and numbered sequentially, beginning with 68.

PATHOGENESIS OF ENTEROVIRUS INFECTIONS

After ingestion of fecally contaminated material, virus implants in susceptible tissues of the pharynx and distal small intestine. Whereas some replication occurs in the pharynx, the primary site of infection is the distal small intestine; virus traverses the intestinal lining cells without causing detectable cytopathology and reaches Peyer's patches in the lamina propria, where significant replication occurs. Within 1 or 2 days, virus spreads to regional lymph nodes and, on about the third day, small quantities escape into the bloodstream (the "minor viremia") and are disseminated throughout the reticuloendothelial system and to other receptor-bearing target tissues. In most cases, infection is contained at this stage by host defense mechanisms with no further progression, resulting in asymptomatic infection. In a minority of infected persons, replication continues in reticuloendothelial tissues producing, by about the fifth day, heavy sustained viremia (the "major viremia") that coincides with the "minor illness" of poliovirus infection and with the "nonspecific febrile illness" caused by other human EVs.

The major viremia disseminates large amounts of virus to target organs, such as the spinal cord, brain, meninges, heart, skeletal muscles, and skin, where further virus replication results in inflammatory lesions and cell necrosis. In most such patients, host defense mechanisms quickly terminate the major viremia and halt virus

Table 184.1 Classification of human enteroviruses (EV)[a]

Enterovirus group	Number of serotypes	Numerical designation	Growth in primate cell culture	Pathogenicity for suckling mice	Pathogenicity for monkeys
Poliovirus	3	1–3	+	–	+
Coxsackievirus, group A	23	A1–A22, A24[b]	+/–[c]	+	–[d]
Coxsackievirus, group B	6	B1–B6	+	+	–
Echovirus	29	1–9, 11–21, 24–27, 29–34[e]	+	–	–
Enterovirus	4	68–71[f] +	Variable	Variable[f]	Variable[g]

[a] Many EV strains have been isolated that do not conform to these criteria.

[b] Coxsackievirus A23 has been reclassified as echovirus 9, leaving 23 Coxsackievirus group A serotypes.

[c] Except for a few serotypes (e.g., A7, A9, A16), primary isolates of group A Coxsackieviruses grow poorly or not at all in cell culture; virus isolation requires inoculation of suckling mice.

[d] Coxsackievirus A7 is neurovirulent in monkeys.

[e] Echovirus 10 has been reclassified as reovirus type 1; echovirus 28 has been reclassified as rhinovirus 1A; echovirus 22 and echovirus 23 have been reclassified as parechovirus 1 and parechovirus 2, respectively, members of a new *Parechovirus* genus that now includes at least 16 serotypes that infect, primarily, male infants less than 1 year of age and cause a wide variety of illnesses. Echovirus 34 is a variant of Coxsackievirus A24.

[f] EV-70 and EV-71 are pathogenic for suckling mice.

[g] EV-70 and EV-71 are neurovirulent in monkeys.

replication in target organs; only rarely is virus replication in target organs extensive enough to be clinically manifest. Serotype-specific neutralizing antibodies may be detected in the serum within 4 or 5 days of infection, and they generally persist for life. Evidence for the critical role of antibodies in terminating infection is provided by the occurrence of chronic persistent EV infections in agammaglobulinemic children. Host defenses do not, however, terminate virus replication in the intestine, and fecal shedding continues for weeks after both symptomatic and asymptomatic EV infections. Immunity to EV is serotype specific; neutralizing antibodies in the blood prevent EV dissemination and disease. Reinfection is relatively uncommon and is confined to the alimentary tract; it is asymptomatic, and the duration of virus shedding is markedly reduced.

EPIDEMIOLOGY

Human EVs are worldwide in distribution, and humans are their only known reservoir. The prevalence of EV infection varies markedly with season and climate, and with the age and socioeconomic status of the population. In tropical and semitropical regions, EV infections are frequent throughout the year. In temperate climates, the incidence of infection is markedly increased in the summer and early fall; within the United States, climatic and socioeconomic factors affect the prevalence of EV infections. EV isolation rates from young children are 2- to 3-fold higher in southern than in northern cities and 3- to 6-fold higher in lower than in middle and upper socioeconomic districts. In the United States, one to three EV serotypes usually predominate in a given location each year. Some serotypes are present each year, whereas others disappear and may re-emerge after years of inactivity.

Transmission of human EV is chiefly by the fecal–oral route directly from person to person or through fomites; spread by respiratory secretions plays a lesser role. After infection by most serotypes, virus can be recovered from the oropharynx and intestine of both symptomatic and asymptomatic individuals, but virus is shed in greater amounts and for a longer period (a month or more) in the feces.

Infants and young children have the highest rates of EV infection and illness, and EVs are most efficiently disseminated by infected children younger than 2 years of age. Spread is facilitated by crowding and poor hygiene. Secondary attack rates in families are 90% for polioviruses, 75% for Coxsackieviruses, and 50% to 70% for echoviruses. Maternal antibodies passively acquired transplacentally or in breast milk prevent or modify EV infections in early infancy,

and may interfere with oral polio vaccine in breastfed infants.

Although the epidemiology of most EVs is similar, patterns of infection with some serotypes are distinctive. EV-70 and Coxsackievirus A24, etiologic agents of acute hemorrhagic conjunctivitis, are transmitted by direct inoculation of the conjunctivae by fingers, fomites, and ophthalmologic instruments contaminated with infected tears. Replication of these viruses in the alimentary tract, if it occurs at all, is limited. Coxsackievirus A21 is shed primarily from the upper respiratory tract, where it produces a rhinovirus-like illness. It is transmitted by respiratory secretions.

The incubation period for EVs varies from less than 1 day to more than 3 weeks, but it is generally 2 to 7 days. It is shortest when symptoms are the result of virus replication at the portal of entry and longest when they reflect tissue injury following viremia (e.g., Coxsackievirus myocarditis).

CLINICAL MANIFESTATIONS OF ENTEROVIRUS INFECTIONS

The majority of nonpolio EV infections (50% to 80%) are asymptomatic. Most symptomatic infections consist of *undifferentiated febrile illnesses* ("summer grippe"), often accompanied by upper respiratory symptoms. These are generally mild and last only a few days. This syndrome is totally nonspecific; it can be caused by any EV serotype. The characteristic EV syndromes, such as aseptic meningitis, hand-foot-and-mouth disease (HFMD), and pleurodynia, are, in fact, unusual manifestations of EV infection.

Some syndromes are associated with certain EV serotypes or subgroups (Table 184.2), but even these associations are not specific. The same syndrome may also be caused by a number of other EV serotypes. Conversely, a single EV serotype may cause several different syndromes, even within the same outbreak.

CENTRAL NERVOUS SYSTEM SYNDROMES

Aseptic meningitis

EVs are responsible for more than 80% of cases of aseptic meningitis in developed countries. Almost every serotype has been implicated. Although attack rates are generally highest in children, cases also occur in adults, especially during larger outbreaks. Initial symptoms, which are typical of the *undifferentiated febrile illness* (e.g., fever, headache, malaise, myalgia, and sore throat), are followed, usually within a day, by signs and symptoms of meningitis, including a more severe headache that is often retrobulbar, photophobia, meningismus, stiffness of the neck and back, and nausea and vomiting, especially in children. The illness is sometimes biphasic like poliomyelitis. The cerebrospinal fluid (CSF) is clear and under slightly increased pressure. The total cell count, which can vary from less than $10/mm^3$ to more than $3000/mm^3$, averages 50 to $500/mm^3$. Initially, neutrophils may predominate (although they rarely exceed 90%), but they are quickly replaced by mononuclear cells. Pleocytosis may be absent in up to 30% of infants and children with EV meningitis diagnosed by CSF PCR assay. The glucose concentration is usually normal, although levels less than 40 mg/dL are occasionally observed. The protein concentration is normal or slightly elevated but rarely exceeds 100 mg/dL. Fever and signs of meningeal inflammation subside in 3 to 7 days, although pleocytosis may persist for an additional week or more. The great majority of children and adults recover fully without sequelae. However, enteroviral meningitis during the first year of life may result in permanent neurologic damage in up to 10% of affected infants, manifested by paresis, reduced head circumference, spasticity, and impaired intellect.

Some cases may be accompanied by a rash, which, if petechial, may raise the specter of meningococcemia.

Paralytic disease

Acute flaccid paralysis (AFP) may occur in the course of many nonpolio EV infections. It is similar but less severe than that caused by polioviruses. Muscle weakness is more common than frank paralysis, and recovery is usually complete, although occasional patients suffer cranial nerve palsies or severe, sometimes fatal, bulbar involvement. In contrast to paralytic poliomyelitis, which in the pre-vaccine era occurred in epidemics, cases of paralysis associated with nonpolio EV are generally sporadic. However, several nonpolio EVs produce AFP with sufficient frequency to cause local outbreaks and epidemics. A variant of Coxsackievirus A7, once thought to be a fourth serotype of poliovirus, has caused outbreaks, as well as numerous sporadic cases of AFP. Paralytic disease resembling poliomyelitis, with a significant incidence of residual paralysis and muscle atrophy, has been observed in patients with acute

Table 184.2 Clinical manifestations of nonpolio enterovirus (EV) infections[a]

Clinical syndrome	Group A Coxsackieviruses[b]	Group B Coxsackieviruses	Echoviruses[c]	Enteroviruses
Asymptomatic infection	All serotypes	All serotypes	All serotypes	All serotypes
Undifferentiated febrile illness ("summer grippe") with or without respiratory symptoms	All serotypes	All serotypes	All serotypes	68, 70, 71
Aseptic meningitis (often associated with an exanthem)	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 14, 16, 17, 18, 22, 24	1, 2, 3, 4, 5, 6	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 16, 17, 18, 19, 20, 21, [22], [23], 25, 30, 31, 33	70, 71
Encephalitis	2, 4, 5, 6, 7, 9, 10, 16	1, 2, 3, 4, 5	2, 3, 4, 6, 7, 9, 11, 14, 17, 18, 19, [22], 25, 30, 33	70, 71
Paralytic disease (poliomyelitis-like)	4, 5, 6, 7, 9, 10, 11, 14, 16, 21, 24	1, 2, 3, 4, 5, 6	1, 2, 4, 6, 7, 9, 11, 14, 16, 17, 18, 19, 30	70, 71
Myopericarditis	1, 2, 4, 5, 7, 8, 9, 14, 16	1, 2, 3, 4, 5, 6	1, 2, 3, 4, 6, 7, 8, 9, 11, 13, 14, 16, 17, 19, [22], 25, 30	
Pleurodynia	1, 2, 4, 6, 9, 10, 16	1, 2, 3, 4, 5, 6	1, 2, 3, 6, 7, 8, 9, 11, 12, 14, 16, 19, [23], 25, 30	
Herpangina	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 16, 22	1, 2, 3, 4, 5, 6	6, 9, 11, 16, 17, [22], 25	71
Hand-foot-and-mouth disease	4, 5, 6[d], 7, 9, 10, 16, 24	2, 5	4, 7, 11, 19	71
Exanthems	2, 4, 5, 6, 7, 9, 10, 16	1, 2, 3, 4, 5, 6	2, 4, 5, 6, 9, 11, 16, 18, 25	71
Common cold	2, 10, 21, 24	1, 2, 3, 4, 5	2, 4, 8, 9, 11, 20, 25	
Lower respiratory tract infections (bronchiolitis, pneumonia)	7, 9, 16	1, 2, 3, 4, 5	4, 8, 9, 11, 12, 14, 19, 20, 21, 25, 30	68[e], 71
Acute hemorrhagic conjunctivitis[f]	24			70
Generalized disease of the newborn	3, 9, 16	1, 2, 3, 4, 5	3, 4, 6, 7, 9, 11, 12, 14, 17, 18, 19, 20, 21, [22], 30	

[a] A great many EV serotypes have been implicated in most of these syndromes, at least in sporadic cases. The serotypes listed are those that have been clearly and/or frequently implicated. Serotypes with the strongest association are underlined.

[b] Because isolation of many of the group A Coxsackieviruses requires suckling mouse inoculation, they are likely to be underreported.

[c] Echovirus types [22] and [23] have been reclassified as parechoviruses 1 and 2, the first members of a new picornavirus genus, *Parechovirus*.

[d] A variant of Coxsackievirus A6 has been associated with mucocutaneous bullous reactions resembling Stevens–Johnson syndrome.

[e] EV-68 (EV-D68) causes severe lower respiratory tract infection in children, most of whom have a history of asthma.

[f] Conjunctivitis without hemorrhage is frequently seen in association with other manifestations in patients infected with many group A and group B Coxsackieviruses and echoviruses, especially Coxsackieviruses A9, A16, and B1–B5, and echoviruses 2, 7, 9, 11, 16, and 30.

hemorrhagic conjunctivitis caused by EV-70. EV-71 is a highly neurotropic virus associated with a variety of central nervous system (CNS) syndromes, including aseptic meningitis, encephalitis, acute cerebellar ataxia, Bell's palsy, AFP, and bulbar poliomyelitis. It has been responsible for large outbreaks of AFP in Eastern Europe, Russia, and Asia.

Encephalitis

Encephalitis is a well-recognized but uncommon manifestation of EV infection. EVs account for only 10% to 20% of the cases of encephalitis of proven etiology in the United States. In most cases, encephalitis complicates the course of aseptic meningitis; parenchymal involvement is indicated by the onset of confusion, coma, abnormalities of motor function, hemiparesis, vasomotor instability, cranial nerve palsies, cerebellar ataxia, and focal or generalized seizures, singly or in various combinations. Cerebral involvement is usually generalized, but focal encephalitis does occur and may be clinically indistinguishable from herpes simplex encephalitis. Recovery from enteroviral encephalitis is usually complete, although neurologic sequelae and deaths do occur, especially in young infants and during EV-71 epidemics. CNS disease is usually preceded by HFMD or herpangina.

OTHER REPORTED NEUROLOGIC COMPLICATIONS

EVs, particularly Coxsackie A viruses, appear to be an important cause of febrile seizures in children during EV season. Other neurologic syndromes, including Guillain–Barré syndrome, transverse myelitis, and Reye's syndrome, have been reported in patients with a number of different EV infections.

EPIDEMIC PLEURODYNIA (BORNHOLM DISEASE)

Epidemic pleurodynia is an acute febrile viral illness characterized by the sudden onset of intense paroxysmal lower thoracic or abdominal pain. Synonyms include Bornholm disease, devil's grip, epidemic myalgia, epidemic benign dry pleurisy, and Sylvest disease. The name *pleurodynia* (*pleura*, "side"; *odyne*, "*pain*") reflects the characteristic intercostal location of the pain and does not connote disease of the pleura. Pleurodynia is usually an epidemic disease, but sporadic cases do occur.

Pleurodynia is characterized by the abrupt onset of fever and sharp, paroxysmal pain over the lower ribs or upper abdomen. In about 25% of patients, this is preceded by a 1- or 2-day prodrome of headache, malaise, anorexia, sore throat, and diffuse myalgia. The pain varies in intensity, but is often severe. It is accentuated, sometimes elicited, by deep breathing, coughing, and movement, and can usually be elicited by pressure on the affected muscles. In adults, the pain is primarily in muscles of the thorax, especially the intercostals. A pleural friction rub is occasionally present. In children, abdominal muscles are more often involved. Occasionally it may involve muscles in the neck or limbs. Palpable, often visible, muscle swelling may be observed.

Multiple paroxysms of pain occur, each lasting from a few minutes to several hours. The initial paroxysm is usually the most severe, and patients frequently appear relatively well between paroxysms. The acute illness generally lasts for 2 to 6 days, with a range of 12 hours to 3 weeks. The disease is often biphasic; the initial pain and fever resolve and the patient is asymptomatic for a day or more, and then the pain and fever recur, frequently at the same site. Rarely, patients will have several recurrences over a period of several weeks or will have a late recurrence after being symptom free for a month or more. Group B Coxsackieviruses, especially B3 and B5, are the principal cause. Transmission is primarily from person to person, and multiple family members may be attacked almost simultaneously or in rapid succession at intervals of 2 to 5 days.

Pleurodynia results from EV infection of skeletal muscle, not of the pleura or peritoneum. As in most enteroviral diseases, infection is initiated in the alimentary tract, with infection of skeletal muscle resulting from viremia. Pleurodynia may be confused with any of a number of more serious diseases. When the pain is thoracic, these include pneumonia, pulmonary infarction, rib fracture, costochondritis, and myocardial infarction. When the pain is abdominal, it can be difficult to differentiate pleurodynia from serious causes of acute abdominal pain, such as peritonitis, cholecystitis, appendicitis, perforated peptic ulcer, and acute intestinal obstruction. Pleurodynia may also be confused with the pain of pre-eruptive herpes zoster, herniated intervertebral disk, and renal colic. Generalized polymyositis and focal myositis often localized to the thighs has also been caused by infections with Coxsackieviruses A9, B2, and B6, and echoviruses 9 and 11. Myoglobinemia and elevated levels of creatine phosphokinase are often present.

Treatment of pleurodynia is symptomatic. Analgesics, as well as heat applied to affected muscles may be useful. Despite the tendency of the disease to relapse, patients with epidemic pleurodynia eventually recover completely.

MYOCARDITIS AND PERICARDITIS CAUSED BY ENTEROVIRUSES

EVs are the major infectious cause of myocarditis and pericarditis in North America and western Europe. Neonatal infections frequently result in severe myocarditis, widespread involvement of other organs, and high mortality, whereas in older children and adults, pericarditis often predominates and the disease is generally benign and self-limited. In fact, cardiac involvement during EV infections is often unrecognized. However, idiopathic dilated cardiomyopathy may be a late sequela of both recognized and unrecognized EV myocarditis.

Endomyocardial biopsy, with *in situ* hybridization and reverse transcription–polymerase chain reaction (RT–PCR), has improved our ability to establish the etiology of myocarditis and pericarditis. The group B Coxsackieviruses are the most common etiologic agents of myocarditis

and pericarditis. They account for 50% of sporadic cases of acute myocarditis and for all cases in epidemics. Human adenoviruses, dengue, and parvovirus B19 are other important causes of myocarditis. Group B Coxsackieviruses account for 30% or more of sporadic cases of acute nonbacterial pericarditis.

Most cases occur in males, but in females the risk of cardiac involvement is increased during pregnancy and immediately postpartum.

Idiopathic dilated cardiomyopathy may represent the end stage of EV myocarditis. This notion is supported by the development of chronic cardiomyopathy in approximately 10% of patients observed long term after group B Coxsackievirus myocarditis and by the demonstration of progressive fibrosis in such patients by serial endomyocardial biopsies.

Treatment of EV myopericarditis is supportive. It includes control of pain, and monitoring for arrhythmias, heart failure, and hemodynamic compromise. Bed rest is an important component of therapy because of evidence in mice with Coxsackievirus B3 myocarditis that exercise increases myocardial necrosis and mortality during the acute disease. Cardiac assist devices may be lifesaving. Corticosteroids should not be administered; their use during the acute phase of viral myocarditis has been associated with rapid clinical deterioration.

The majority of children and adults with enteroviral myopericarditis recover without sequelae. Acute mortality is low (0% to 5%), and deaths result from arrhythmias or congestive heart failure in patients with myocarditis; cardiac tamponade is extremely rare in enteroviral pericarditis.

Approximately 20% of patients experience one or more episodes of recurrent myopericarditis within 1 year of their initial illness, and persistent electrocardiographic (ECG) abnormalities are observed in 10% to 20% of patients. Cardiomegaly persists in 5% to 10% of patients, and long-term follow-up suggests that 10% or more may develop chronic cardiomyopathy. Constrictive pericarditis rarely occurs following enteroviral pericarditis.

INSULIN-DEPENDENT DIABETES MELLITUS

Epidemiologic evidence suggests a role for EV, especially group B Coxsackieviruses, in the etiology of insulin-dependent diabetes mellitus (IDDM). A number of serologic studies have found evidence of a higher frequency of Coxsackievirus B infection in children with new-onset IDDM than in matched controls, and maternal EV infections during pregnancy have been associated with the subsequent development of IDDM in offspring during early childhood. Moreover, enteroviral RNA has been identified by RT–PCR in children with new-onset IDDM at a higher frequency than in matched controls, and Coxsackieviruses B4 and B5 have been identified in pancreatic tissue of children dying of ketoacidosis at the onset of IDDM.

MUCOCUTANEOUS SYNDROMES CAUSED BY ENTEROVIRUSES

EVs are the leading cause of exanthematous disease in the United States and other developed countries. Almost all EVs can cause maculopapular eruptions, and most serotypes may cause petechial or papulovesicular exanthems and enanthems. Moreover, a given EV may cause more than one pattern of mucocutaneous disease, even within a single infected household. Consequently, except for HFMD, which is usually caused by Coxsackievirus A16 or EV-71, there are no clinical or epidemiologic characteristics of any given EV rash that point to a specific EV as its cause.

The epidemiology of EV exanthems and enanthems is the epidemiology of EV infections in general. The vast majority occur during the summer and early fall. The incidence of enanthems and exanthems in infected persons varies among different EVs and even among different strains of the same EV. For example, enanthems and exanthems are often seen in >50% of infected children during outbreaks of infection caused by echovirus 9 or Coxsackievirus A16 but are rare during outbreaks caused by echovirus 6 or Coxsackievirus A7. Host factors, especially age, are also important; infants and young children are more likely to develop mucocutaneous lesions, whereas other manifestations of EV infection, such as aseptic meningitis, are more likely to develop in older children and adults. Thus, during outbreaks of echovirus 9 infection, rash is often seen in the majority of infected children younger than 5 years of age, but in less than 5% of infected adults, and it is not uncommon when evaluating an adult with aseptic meningitis and no rash to find that a child in the same household is convalescing from an illness characterized by a maculopapular rash. Enteroviral lesions in the oropharyngeal mucosa

and skin are manifestations of a systemic virus infection, in contrast to the pathogenesis of the lesions of acute herpetic gingivostomatitis, human papillomavirus infections (warts), and acute hemorrhagic conjunctivitis, which are the direct result of exogenous virus infection and replication in epithelial cells at the portal of entry.

The obligatory alimentary tract replication and viremia before mucocutaneous lesions develop explains the 3- to 10-day incubation period and the frequent occurrence of prodromal signs and symptoms. Moreover, the simultaneous dissemination of virus to a number of target organs explains the concurrent appearance of other manifestations of EV infection, such as aseptic meningitis and myopericarditis.

Enanthems

The oropharyngeal mucosa is involved to some degree during most symptomatic enteroviral infections. This is usually manifest by mild pharyngitis and mucosal erythema, but it may also result in a variety of enanthems. These may consist of macules, papules, vesicles, petechiae, or ulcers, and they may occur alone or in association with exanthems and other manifestations of systemic enteroviral infection. They are often transient and frequently unrecognized, but they occasionally lead to diagnostic confusion, for example, when they resemble Koplik spots and accompany a morbilliform exanthem in a child infected by echovirus 9. Two enanthems are sufficiently unique to warrant separate description.

HERPANGINA

Herpangina is a syndrome characterized by sudden onset of fever, sore throat, pain on swallowing, and a vesicular enanthem of the posterior pharynx. It is seen primarily in children between ages 3 and 10. The disease begins abruptly, after a 3- to 10-day incubation period, with fever, sore throat, and pain on swallowing. There may also be anorexia, vomiting, and abdominal pain. Fever tends to be greater in younger children, who may suffer febrile convulsions; older children and adults frequently complain of headache and myalgia. On examination there is pharyngeal erythema but little or no tonsillar exudate. The characteristic lesions are discrete 1- to 2-mm vesicles and ulcers surrounded by 1- to 5-mm zones of erythema. Lesions are few, averaging 4 to 5 per patient, with a range of 1 or 2 to 20. They occur on the anterior tonsillar pillars, the posterior edge of the soft palate, and the uvula, and less frequently on the tonsils, the posterior pharyngeal wall, and the posterior buccal mucosa. They begin as small papules, progress to vesicles, and ulcerate within 24 hours. The shallow ulcers, which are moderately painful, may enlarge over the next 1 or 2 days to a diameter of 3 to 4 mm. Symptoms generally disappear in 3 or 4 days, but the ulcers may persist for up to a week. Most cases are mild and resolve without complications, but herpangina is occasionally associated with exanthems, aseptic meningitis, or other serious manifestations of systemic EV infection.

Outbreaks of herpangina are common during the summer, and sporadic cases are also observed. Group A Coxsackieviruses account for the majority of outbreaks.

ACUTE LYMPHONODULAR PHARYNGITIS

Acute lymphonodular pharyngitis is a variant of herpangina that has been described in children infected with Coxsackievirus A10. The lesions have the same distribution as typical cases of herpangina, but instead of evolving into vesicles and ulcers, they remain papular and are infiltrated with lymphocytes to form 2- to 3-mm gray-white nodules surrounded by narrow zones of erythema. The disease is otherwise indistinguishable from herpangina.

HAND-FOOT-AND-MOUTH DISEASE

HFMD (vesicular stomatitis with exanthem) is a mild enteroviral disease characterized by a vesicular eruption in the mouth and over the extremities. It occurs most frequently in children younger than 5 years of age. After an incubation period of 3 to 6 days, the disease begins with mild fever ranging from 38°C to 39°C, anorexia, malaise, and, often, a sore mouth. Within 1 or 2 days vesicular lesions appear in the oral cavity, most frequently on the anterior buccal mucosa and the tongue, but also on the labial mucosa, gingivae, and hard palate. In the majority of preschool children, but in only about 10% of infected adults, the oral lesions are accompanied by vesicular skin lesions, most often on the dorsal or lateral surfaces of the hands and feet and on the fingers and toes but not infrequently on the palms and soles. Less often, lesions occur on the buttocks or more proximally on the extremities and, rarely, on the genitalia. They are generally 3 to 7 mm in diameter and surrounded by a narrow zone of erythema. They range from 2 or 3 to 30 or more. HFMD is caused most frequently by Coxsackievirus A16; less frequently by EV-71 and Coxsackieviruses A5, A9, and A10; and occasionally by Coxsackieviruses A4, A7, B2, and

B5. Outbreaks and sporadic cases occur primarily in the summer and early fall. HFMD may be accompanied by more serious manifestations, especially when caused by EV-71. A variant of Coxsackievirus A6 has been associated with widespread mucocutaneous bullous lesions resembling Stevens–Johnson syndrome.

Exanthems

EV exanthems themselves are benign, but they are clinically important for at least three reasons: (1) They constitute direct evidence of EV dissemination and thus provide a clue to the presence and the etiology of coexistent disease referable to other infected target organs, such as the heart and the CNS; (2) they represent the "tip of the iceberg" of EV infection in the community; and (3) they are often confused with other infectious exanthems, some of which have more serious consequences, require specific control measures, or are amenable to specific anti-infective therapy. Misdiagnosis of EV rashes assumes added significance as we consider the threat of bioterrorism involving the use of smallpox.

The most common cutaneous manifestation of EV infection is an erythematous maculopapular rash that appears together with fever and other manifestations of systemic infection. This is also a common manifestation of infection by a variety of other organisms, but it is more often caused by EV. Only certain EVs (e.g., echovirus 9) cause this syndrome with high frequency, but almost all can produce it at least occasionally. The rash begins on the face and quickly spreads to the neck, trunk, and extremities. It consists of 1- to 3-mm erythematous macules and papules that may be discrete (*rubelliform*, resembling rubella) or confluent (*morbilliform*, resembling measles). It usually lasts for 2 to 5 days and does not itch or desquamate. Enteroviral exanthems are generally not accompanied by significant lymphadenopathy. Enteroviral rashes are sometimes petechial and occasionally purpuric, most frequently in echovirus 9 and Coxsackievirus A9 infections.

Vesicular exanthems are most often seen as a component of HFMD (see earlier), but several EVs, including echovirus 11, Coxsackievirus A9, and EV-71, may cause vesicular exanthems without an associated enanthem. The lesions resemble those caused by varicella-zoster and herpes simplex viruses. In contrast to varicella, however, vesicular rashes caused by EV are usually peripheral in distribution and consist of relatively few lesions that heal without crusting. When they are not associated with HFMD, vesicular lesions caused by EV are often confused with insect bites or poison ivy. Echovirus 11 and several Coxsackievirus serotypes have been associated with skin lesions resembling papular urticaria, lesions that usually result from insect bites.

Enteroviral rashes are generally accompanied by fever; they develop at or within 1 or 2 days of its onset. In some cases, however, the rash does not develop until the fever subsides, a pattern resembling that of *roseola infantum* (exanthem subitum), caused by human herpesvirus 6.

Herpangina is most often confused with bacterial pharyngitis, tonsillitis, or pharyngitis caused by other viruses. Other considerations include HFMD, primary herpes simplex virus infections, particularly acute herpetic pharyngotonsillitis, and herpes zoster involving the palate.

The vesicular lesions of HFMD resemble those caused by herpes simplex and varicella-zoster viruses. Patients with primary herpetic gingivostomatitis usually have more toxicity, cervical lymphadenopathy, and more prominent gingivitis. Their cutaneous lesions are usually perioral but may occasionally involve a finger that has been in the mouth. Recurrent herpes simplex (herpes labialis) usually involves the vermillion border of the lip or the adjacent skin, is rarely accompanied by lesions on the hands or feet, often has a neuralgic prodrome, and frequently has a history of recurrent episodes. The cutaneous lesions of varicella are generally more extensive and are centrally distributed, sparing the palms and soles. Oral lesions are far less prominent in varicella, and its prevalence in winter and spring further distinguish it from HFMD. Like vesicular lesions caused by herpes simplex and varicella-zoster virus, EV vesicles are generally more superficial and evolve more rapidly than those caused by variola and vaccinia viruses.

Aphthous stomatitis is distinguished from HFMD by the absence of fever and other signs of systemic illness, the absence of cutaneous lesions, and often by a history of recurrence. Maculopapular exanthems caused by EV are distinguished from measles and rubella by their summertime occurrence; the usual absence of posterior cervical, suboccipital, and postauricular lymphadenopathy; and their relatively short incubation period. The absence of significant coryza and conjunctivitis further distinguishes the typical enteroviral exanthems from measles. In addition, the probability of measles and rubella

is markedly reduced in persons with a well-documented history of adequate immunization.

When enteroviral rashes are maculopapular they may be confused with drug reactions; when they are petechial they may be confused with bacterial or rickettsial rashes. When enteroviral rashes are petechial or purpuric it is impossible to rule out meningococcemia on clinical grounds alone, and when the rash is associated with aseptic meningitis (as is often the case in echovirus 9 and Coxsackievirus A9 infections), it is clinically indistinguishable from meningococcal meningitis. Enteroviral enanthems and exanthems are generally benign self-limited illnesses that require only symptomatic therapy for headache and sore throat. When illness mimics meningococcemia or meningococcal meningitis, antimicrobial chemotherapy should be initiated until bacterial infection is ruled out.

RESPIRATORY TRACT DISEASE CAUSED BY ENTEROVIRUSES

A number of EVs have been associated with mild upper respiratory tract illness in children and adults, especially Coxsackieviruses A21, A24, and B1 through B5 and echoviruses 9 and 11. Many produce illnesses that resemble the common cold. In contrast to most other EVs, Coxsackievirus A21 is shed primarily from the upper respiratory tract rather than in feces. EVs have also been associated with childhood tracheitis, bronchitis, croup, bronchiolitis, and pneumonia. Surveillance data indicate that EVs account for 2% to 10% of viral respiratory disease and that 10% to 15% of symptomatic EV infections are associated with respiratory symptoms. The respiratory illnesses caused by EVs are clinically indistinguishable from similar illnesses caused by viruses more commonly considered to be respiratory tract pathogens, such as rhinoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial virus, and adenoviruses. However, infections with these viruses occur most frequently during the winter, whereas EV infections occur primarily in the summer and early fall. EV-68 (EV-D68) infections were uncommon until very recently. In 2014, EV-68 has caused a national epidemic of severe, sometimes fatal, lower respiratory tract infection in children. Symptoms resemble asthma, with respiratory distress and hypoxia, often requiring ICU admission. Most of the cases have a history of asthma and are afebrile.

ACUTE HEMORRHAGIC CONJUNCTIVITIS

Acute hemorrhagic conjunctivitis (AHC) is an acute, highly contagious, self-limited disease of the eye characterized by sudden onset of pain, photophobia, conjunctivitis, swelling of the eyelids, and prominent subconjunctival hemorrhages. AHC has occurred in explosive epidemics throughout the world.

AHC is highly contagious. In contrast to most enteroviral infections, it is transmitted by direct inoculation of the conjunctivae with virus-contaminated fingers or fomites or ophthalmologic instruments. EV-70 and the Coxsackievirus A24 variant are temperature-sensitive viruses that replicate optimally at 33°C to 35°C, the temperature of the conjunctivae. During epidemics, all age groups are affected.

AHC begins with the sudden onset of eye pain and foreign-body sensation, lacrimation, photophobia, blurred vision, and bulbar conjunctivitis. Signs and symptoms rapidly increase in severity with the development of palpebral conjunctivitis, conjunctival edema, swelling of the eyelids, subconjunctival hemorrhages in the bulbar conjunctivae, and a serous or seromucoid ocular discharge containing large numbers of polymorphonuclear leukocytes. Subconjunctival hemorrhages are the hallmark of the disease. AHC often begins unilaterally, but it rapidly spreads to the other eye. Signs and symptoms peak within 24 to 36 hours of onset, by which time most patients have also developed hypertrophy of palpebral follicles and papillae, preauricular lymphadenopathy, and punctate epithelial keratitis with tiny corneal erosions.

Poliomyelitis-like motor paralysis occurs as a rare complication of AHC caused by EV-70, but not in AHC caused by Coxsackievirus A24. It occurs predominantly in adult males. The neurologic disease generally does not begin until 2 to 5 weeks after AHC (range of 5 to 60 days or more), thus its relationship to the conjunctivitis is often overlooked.

Treatment is symptomatic. Topical antihistamine/decongestant eyedrops and cold compresses may reduce discomfort. Corticosteroids are contraindicated. Transmission of AHC can be prevented by careful handwashing, avoidance of contaminated washcloths and towels, and sterilization of all ophthalmologic instruments.

DIAGNOSIS

The enteroviral etiology of a disease may be suspected on clinical and epidemiologic grounds, but the multiplicity of agents capable of causing most clinical syndromes associated with EV infections makes it impossible to establish a specific etiologic diagnosis on the basis of such information alone. Virus isolation from the site of pathology (e.g., CSF in aseptic meningitis, brain biopsy in encephalitis, myocardial tissue and pericardial fluid in myopericarditis) has been the "gold standard" of enteroviral diagnosis. Isolation of an EV from the nasopharynx or feces is less definitive, because isolation of an EV from these sites may be due to an intercurrent asymptomatic EV infection or prolonged virus shedding from an earlier EV infection and be etiologically unrelated to the observed illness.

The recent availability of methods for the detection and identification of EV RNA via RT–PCR makes it possible to provide an accurate diagnosis of EV infection within a few hours, with a sensitivity greater than virus isolation and a specificity of 100%. Amplification permits identification of most EVs, whereas sequencing a portion of the gene encoding VP1 can yield a serotype-specific diagnosis. Serologic testing has a very limited role because of the diversity of serotypes and the lack of a common antigen.

TREATMENT AND PREVENTION

Specific antiviral chemotherapeutic and chemoprophylactic agents are not yet available for EV infections. Thus treatment is symptomatic. Corticosteroids should not be administered during acute EV infections. Strenuous exercise and intramuscular injections, both of which may precipitate paralysis of the involved muscles during EV viremia, should also be avoided during the acute, presumably viremic, phase of symptomatic EV infections. Intravenous immunoglobulin (IVIG), which contains high titers of neutralizing antibodies to many EVs, appears to have been useful in some agammaglobulinemic patients with chronic enteroviral meningoencephalitis. IVIG may also have a role in the treatment of enteroviral infections in patients with compromised B-lymphocyte function. Infants with generalized neonatal EV infections are unlikely to have received transplacental antibodies to the causative virus from their mothers. Consequently it seems reasonable to administer IVIG to such infants in an attempt to terminate their viremia and limit virus replication in infected tissues. Prophylactic IVIG should also be considered for patients with compromised B-lymphocyte function, including bone marrow transplant recipients. Several promising inhibitors of EV replication belong to a class of anti-EV drugs known as capsid-binding inhibitors or (WIN) compounds that bind within a hydrophobic pocket under the floor of the receptor-binding canyon in the EV capsid. One of these compounds, pleconaril, has broad and potent anti-EV activity, excellent bioavailability, and a very favorable safety profile. Clinical trials have demonstrated benefit in children and adults with EV meningitis and in adults with respiratory infections caused by EV and rhinoviruses. However, the drug is not currently available. Live attenuated and inactivated poliovirus vaccines have been remarkably successful in preventing paralytic poliomyelitis. An inactivated EV-71 vaccine has recently demonstrated efficacy in a large phase III clinical trial.

Pre-exposure administration of immune serum globulin reduces the risk of paralytic poliomyelitis. Because immune serum globulin also contains neutralizing antibodies to many nonpolio EVs, it would probably prevent many nonpolio EV diseases as well. This approach probably reduces the frequency of severe enteroviral infections in agammaglobulinemic patients receiving replacement therapy. However, the benign nature of most EV infections, the fact that exposures are rarely recognized (most result from contact with an asymptomatically infected person), and the relatively short half-life of exogenous immune serum globulin make this approach to prevention impractical in most situations. Nursery outbreaks of severe enteroviral disease provide an exception. The administration of IVIG to all infants in the nursery offers protection to those infants without transplacentally acquired neutralizing antibody who have not yet been infected.

185. Epstein–Barr virus and other causes of the mononucleosis syndrome

Jeffery L. Meier

Epstein–Barr virus (EBV) will infect nearly everyone at some point during his or her lifetime. In the United States, EBV is acquired by ~85% of non-Hispanic black and Mexican-American children by age 14, ~52% of non-Hispanic white children by age 14, and ~95% of all persons by the end of their third decade of life. Lower socioeconomic status increases likelihood of acquiring EBV in childhood.

Oropharyngeal epithelial cells (e.g., in tonsillar crypts) are the source of infectious EBV in saliva. Close oral contact with infectious saliva, i.e., via kissing, is the primary mode of EBV transmission. Sexual intimacy increases EBV transmission risk during adolescence and early adulthood. Casual contact does not transmit the infection. EBV-seropositive donor blood products and tissues may transmit infection, when EBV reactivates from latently infected B lymphocytes.

Table 185.1 EBV-related illness

Acute
Infectious mononucleosis (IM)
Atypical IM presentations or complications
Chronic
Chronic active infection (rare)
Oral hairy leukoplakia
Lymphoproliferative disorders
From congenital or acquired immunosuppression
X-linked (Duncan disease)
Other disorders
African Burkitt's lymphoma
Nonkeratinizing nasopharyngeal carcinoma
Primary central nervous system lymphoma in AIDS
Rare types of smooth muscle cell tumors and thymomas
Hodgkin's disease (EBV DNA in 40%–65% of tumors)

Abbreviations: EBV = Epstein–Barr virus; AIDS = acquired immunodeficiency syndrome.

INFECTIOUS MONONUCLEOSIS

Presentation

Most EBV infections go unnoticed. EBV-related illness, should it develop, varies in spectrum of presentation (Table 185.1). Infectious mononucleosis (IM) is the paradigmatic EBV illness. This is an acute or subacute illness that occurs 5 to 7 weeks after EBV is acquired and corresponds to an overly exuberant immunologic reaction. Rates of this illness are highest for adolescents and young adults ages 15 to 25, and approximately 50% to 80% of college students experience an IM-like illness after a primary EBV infection. Infants and young children seldom exhibit an IM-like illness after a primary EBV infection. Older adults retain the ability to develop the illness but most persons in this age group have already been EBV infected.

Finding a distinctive set of clinical and non-specialized laboratory abnormalities is usually sufficient to make the EBV IM diagnosis (Table 185.2). The EBV IM diagnosis is highly likely in persons presenting with the clinical triad of fever, pharyngitis, and cervical lymphadenopathy; absolute peripheral lymphocytosis; atypical lymphocytosis that is >10% of the differential; and heterophile antibodies. As these criteria are relaxed, the probability of EBV causing the mononucleosis (mono)-like syndrome decreases accordingly. Conversely, failure to fulfill these criteria does not rule out EBV. Heterophile antibody is not detected in approximately 5% to 20% of EBV IM cases and might not become detectable until later in the illness. Atypical lymphocytosis may not peak until later in the illness. Unusual clinical presentations are more likely to occur in infants, young children, older adults, and immunosuppressed persons.

Malaise and fatigue are often prominent IM symptoms, may take more time to resolve than other symptoms, and tend to linger for longer periods in patients having higher severity of acute illness. Convalescence for fatigue and impaired functional status occasionally drags

Signs	Lymphadenopathy, fever, pharyngitis	Splenomegaly, hepatomegaly, palatal petechiae, periorbital edema	Rash, jaundice Oral or genital ulcers
Labs	>50% mononuclear cells >10% atypical lymphocytes Heterophile antibodies Mild LFT increase Mild thrombocytopenia Cold agglutinins	Mild neutropenia Antinuclear antibodies Rheumatoid factor Cardiolipin antibodies	Bilirubinemia >3 mg/100 mL Hematuria Pyuria Proteinuria

Abbreviation: LFT = liver function test.

out to 6 months after the acute illness, but this is neither the result of EBV activity nor marked by abnormal physical examination, serological, or laboratory findings. In a recent study, sore throat was the most common IM symptom in young adults. Mild retro-orbital headache is common and short-lived. Upper respiratory tract symptoms may also be present.

Fever in the range of 38°C to 39.5°C (+/− sweats and chills) is common, subsides in 1 to 2 weeks, and rarely persists for up to 4 weeks. Fever above 40°C should prompt a search for superimposed bacterial infection (i.e., bacterial pharyngitis or peritonsillar abscess). Exudative tonsillopharyngitis is a common finding in EBV IM and usually resolves in the first 2 weeks of illness. Petechiae may appear on the uvula and at the junction of soft and hard palates. Symmetric posterior cervical lymphadenopathy elevates IM in the differential diagnosis, whereas anterior cervical lymphadenopathy has many potential etiologies. EBV IM-related lymphadenopathy may take several weeks to resolve. Splenomegaly is common. Mild abdominal discomfort may be present. Severe abdominal pain or left upper quadrant abdominal pain radiating to the left shoulder raises concern of splenic rupture or infarction. Biochemical findings of mild-to-moderate hepatitis are common, though transaminase levels >500 IU/L and jaundice are possible. Rash is infrequent in adolescents and adults; it typically appears as a faint morbilliform eruption. Peripheral blood lymphocytosis often peaks during the second or third week of illness. Mild neutropenia and thrombocytopenia are common.

In elderly persons, the illness of primary EBV infection is less likely to include pharyngitis, lymphadenopathy, splenomegaly, and atypical lymphocytosis, and is more likely to have unusual features, i.e., jaundice or prolonged febrile course. Infants and young children are more likely to have a heterophile-negative illness with coryza, exudative pharyngitis, rash, and hepatosplenomegaly.

Table 185.3 Complications of infectious mononucleosis

Neurologic Encephalitis, meningitis, cerebellitis, Guillain–Barré syndrome, Bell's palsy, optic neuritis, psychosis, polyradiculitis, transverse myelitis, Reye's syndrome
Splenic Rupture of enlarged spleen (traumatic or spontaneous), splenic infarction
Respiratory Upper airway obstruction from hypertrophy of lymphoid tissue, interstitial pneumonitis
Hematologic Autoimmune hemolytic anemia, severe thrombocytopenia, agranulocytosis, aplastic anemia, hemophagocytic syndrome
Hepatic Fulminant hepatitis, hepatic necrosis
Cardiac Myocarditis, pericarditis
Immunologic Anergy, lymphoproliferative syndromes, hypogammaglobulinemia
Dermatologic Cold-mediated urticaria, leukocytoclastic vasculitis, ampicillin-associated rash, erythema multiforme, erythema nodosum

Complications

Approximately 1% of persons with EBV IM experience a complication. Various types of complications are possible (Table 185.3). In some cases, the complication overshadows the other

IM features or is not accompanied by typical IM symptoms or signs. Most complications resolve without sequelae. Rare fatalities have resulted from encephalitis, splenic rupture, hepatic failure, myocarditis, or neutropenia-associated sepsis. Impending airway obstruction results from tonsillar lymphoid hyperplasia and edema. Enlarged spleens are susceptible to traumatic rupture; spontaneous rupture or infarction is rare. Hemolytic anemia, thrombocytopenia, or neutropenia may develop in relation to autoantibody production. Cytopenia is usually self-limiting. Aplastic anemia and hemophagocytic syndrome are rare life-threatening complications. Neurologic complications take on forms of encephalitis, cerebellitis, meningitis, optic neuritis, peripheral neuritis, facial nerve palsy, and Guillain–Barré syndrome.

EBV IM may evolve into a life-threatening lymphoproliferative disorder in persons with profound acquired or congenital cellular immunodeficiency. In a rare inherited disease, the X-linked lymphoproliferative syndrome, young males develop fulminant EBV IM. Many die of hemorrhage and infection; survivors have aplastic anemia, dysgammaglobulinemia, and lymphoma. EBV very rarely causes chronic active infection that results in interstitial pneumonitis, massive lymphadenopathy, hepatosplenomegaly, bone marrow failure, dysgammaglobulinemia, Guillain–Barré syndrome, and uveitis. These patients have high EBV burden in blood or tissues, as well as very high titers of EBV-specific antibodies. Chronic fatigue syndrome is not driven by EBV, but does rarely follow an acute EBV IM episode.

Laboratory testing

Serum heterophile IgM antibodies of the Paul–Bunnell–Davidsohn type are a reliable proxy indicator of EBV IM. These antibodies are distinguished from Forssman and serum sickness heterophile antibodies (that also bind to animal red blood cell components), may not be detected until the second or third week of illness, and fade away in 3 to 6 months. Their levels do not correlate with severity of illness. Contemporary methods of standard, automated, and point-of-care heterophile antibody testing rarely find presence of these antibodies in sera of patients with other clinical conditions, i.e., viral hepatitis, primary human immunodeficiency virus (HIV) infection, malaria, babesiosis, and lymphoma.

EBV-specific antibody testing is performed when key features of IM are lacking or atypical. Measurement of antibodies against viral capsid antigen (anti-VCA) and EBV nuclear antigens (anti-EBNA) in immunocompetent persons is usually sufficient to provide the results needed to confirm or reject the diagnosis of primary EBV infection. Detection of anti-VCA IgM, which is present in 85% to 95% of IM cases, substantiates the diagnosis. Anti-VCA IgM fades away in weeks to months after the acute illness. Anti-VCA IgG seroconversion from negative to positive detection in acute illness and convalescence, respectively, is confirmation of the diagnosis. However, anti-VCA IgG seroconversion is an infrequent finding, because anti-VCA IgG is often near peak level during the acute illness. Anti-VCA IgG persists for life. Undetectable levels of anti-EBNA antibodies in conjunction with presence of anti-VCA IgM or IgG also marks a primary EBV infection. Anti-EBNA antibodies usually become detectable in convalescence and persist for life.

Interpret EBV-specific antibody levels cautiously, as these values may differ by place and method or be confounded by some types of preexisting or coincident conditions. EBV-specific antibody tests are not validated for use in immunosuppressed patient populations and can produce misleading or ambiguous results in this population. Primary cytomegalovirus (CMV) infection in an otherwise normal host may result in detection in EBV VCA IgM as a consequence of either EBV immune-reactivation (the VCA IgM binds to EBV antigen and anti-EBNA antibodies are present) or nonspecific IgM reactivity.

PCR-based measurement of EBV DNA load in serum or plasma may have an auxiliary role as a diagnostic supplement in serologically indeterminate EBV infections. IM in otherwise healthy persons results in release of fragmented EBV DNA in serum or plasma that does not continue for long. The magnitude of EBV DNA load correlates with severity of the acute illness. Although an international World Health Organization (WHO) standard reference for EBV DNA quantification helps standardize PCR test results, major questions remain about the positive and negative predictive values of the various types of PCR assays for the diagnosis of EBV IM.

OTHER CAUSES OF MONO SYNDROME

A mononucleosis-like (mono) syndrome may result from other etiologies. CMV, toxoplasma, HIV, rubella, hepatitis viruses, and other causes of acute pharyngitis are often considered in the list of etiologic possibilities. Clinical and non-

specialized laboratory findings may help distinguish these other etiologies from EBV (Table 185.4). However, the definitive diagnosis usually rests on the results of pathogen-specific laboratory tests (Table 185.5). EBV should be included in the differential diagnosis of heterophile-negative mono syndrome.

Primary CMV infection accounts for the majority of heterophile-negative mono episodes (see Chapter 182, Cytomegalovirus). CMV mono may closely resemble EBV IM. Both CMV and EBV characteristically produce fever, hepatitis, and atypical lymphocytosis. Cervical lymphadenopathy and pharyngitis tend to be milder in CMV mono. Primary CMV infection in the immunocompetent patient is confirmed by serologic evidence of a positive anti-CMV IgM plus low-avidity anti-CMV IgG index or CMV IgG seroconversion. Detection of CMV antigen or DNA in peripheral blood also supports the diagnosis.

Acute retroviral syndrome (ARS) caused by primary HIV infection may manifest as a mono syndrome. In ARS, rash is anticipated, exudative pharyngitis is infrequent, tonsillar hypertrophy is minimal, and oral or genital ulcers are sometimes observed. A transient peripheral lymphopenia may be followed 2 to 3 weeks later by lymphocytosis, in which a small proportion of cells may be reactive. Detection in blood of HIV RNA or p24 antigen but not HIV antibody (or an indeterminate confirmatory result for HIV antibody) is indicative of a primary HIV infection.

Streptococcal pharyngitis is more frequently abrupt in onset than is EBV pharyngitis. Viruses – such as respiratory viruses and some nonpolio enteroviruses – are the most common cause of acute pharyngitis. These viral and bacterial causes of acute pharyngitis do not typically produce hepatosplenomegaly, atypical lymphocytosis, or prominent posterior cervical lymphadenopathy. Adenovirus is exceptional in that it is a common cause of mono-like symptoms in young children and can occasionally produce atypical lymphocytosis. Toxoplasma-induced mono syndrome is uncommonly encountered in the United States and does not produce exudative pharyngitis or peripheral atypical lymphocytosis exceeding 10% of the differential. Rubella also

causes fever and lymphadenopathy, but the additional features of rash, coryza, arthralgias, and minimal atypical lymphocytosis helps distinguish the German measles from EBV IM. Viral hepatitides A to E are usually not accompanied by a troubling level of pharyngitis or marked lymphadenopathy. Acute mono-like illness has also been described for human herpesvirus 6 (HHV-6), herpes simplex, parvovirus B19, nonpolio enteroviruses, lymphohematologic disorders, and systemic drug reactions (e.g., phenytoin, carbamazapine, minocycline, and sulfa drugs).

MANAGEMENT

Epstein–Barr virus

The management of EBV IM rarely demands more than general supportive care, which includes adequate rest, hydration, antipyretics, and analgesics. Acetaminophen is commonly used. Aspirin should be avoided because of the potential risk of bleeding or thrombocytopenia. Complications of IM may require additional supportive measures – e.g., maintenance of airway during obstructive tonsillar enlargement or encephalitis, transfusions for severe hemolytic anemia or thrombocytopenia, splenectomy for splenic rupture. Activity should be restricted in proportion to the degree of symptoms and any splenomegaly. Most students can return to school in less than 2 to 3 weeks.

Enlarged spleens are structurally weakened by mononucleosis and at risk of rupture by trauma. Reported cases of splenic rupture have almost always occurred within the first month after illness onset, though splenic rupture at 7 weeks has been reported. Ultrasonography detects splenomegaly that is not appreciated on physical examination, and non-palpable splenomegaly usually

resolves in 4 to 6 weeks. This supports expert opinion that contact sports should be avoided for 4 to 6 weeks after symptom onset or until absence of splenomegaly is verified. A 2008 consensus statement in sports medicine warns against using one-time ultrasonography imaging for determining presence of splenomegaly and risk of rupture. Normal spleen size is significantly larger for tall athletes, and spleen size in IM-associated splenomegaly may not exceed the normal range. In a prospective study, serial use of ultrasonography in 17 college-aged athletes with EBV IM revealed splenic enlargement in all subjects that peaked within 23 days from time of symptom onset (mean 12.3 days; SD 5.3 days), and subsequently decreased in size ~1% per day on average. While serial use of ultrasonography may increase accuracy in determining the timeframe for resolution of splenomegaly, the cost-effectiveness and reliability of this strategy have been questioned. The athlete (or legally authorized representative) should be informed about issues pertaining to risk of splenic rupture when deciding together whether the athlete can return to contact sports.

EBV IM-associated exudative tonsillopharyngitis commonly leads to a search for β-hemolytic streptococci. Anywhere from 3% to 30% of surveillance throat cultures obtained during IM grow group A streptococci, reflecting the range in prevalence of community streptococcal carriage. Up to 30% of individuals harboring this bacterium eventually show serologic evidence of streptococcal infection. Treatment is with penicillin (500 mg twice daily) for 10 days or an alternative antibiotic selected according to recommendations issued in the Infectious Disease Society of America (IDSA) Practice Guidelines, which are publically accessible. This treatment also prevents poststreptococcal sequelae. One retrospective study concludes that risk of rash from oral amoxicillin is not increased in EBV IM, unlike early reports for ampicillin.

Acyclovir, ganciclovir, and foscarnet inhibit EBV replication during lytic infection but do not inhibit amplification of latent EBV genomes in proliferating B cells. Oropharyngeal shedding of EBV in persons with IM is greatly inhibited by valacyclovir, an orally administered prodrug of acyclovir, and acyclovir given in intravenous or high-dose oral formulations. Suppression of EBV shedding by the antiviral drug is not undermined by concomitant corticosteroid therapy, and the shedding returns after discontinuation of the antiviral agent. However, the collective evidence from several controlled trials indicates that acyclovir is not clinically beneficial in acute EBV IM, and the proportion of circulating B cells containing EBV is not consistently reduced. Clinicians may consider using antiviral therapy as an adjunct to corticosteroid therapy for serious complications of EBV IM.

Use of a corticosteroid for treatment of uncomplicated IM is not recommended. Several small controlled trials of varying design have not consistently found corticosteroid to be clinically beneficial and have not fully addressed the potential adverse effects. Studies showing benefit reveal modest reduction in duration of fever and tonsillopharyngeal symptoms. In a double-blinded, placebo-controlled study, the combination of prednisolone and acyclovir did not significantly decrease duration of IM symptoms. Corticosteroids have not been shown to decrease lymphadenopathy or hepatosplenic disease. Rare anecdotal reports have associated corticosteroid use with encephalitis, myocarditis, and peritonsillar abscess. The possibility of corticosteroid adversely affecting long-term immunity or number of latently infected cells with malignancy potential is a theoretical concern that has not been adequately addressed.

Corticosteroids appear to be useful in the management of certain IM complications. Corticosteroids may quickly ameliorate impending airway obstruction from tonsillar enlargement. A short course of a corticosteroid may also be considered in exceptional situations of severe protracted IM (i.e., fever, prostration, weight loss). Corticosteroids may reduce the severity of autoimmune thrombocytopenia and hemolytic anemia, and their use can be considered for intractable cases of encephalitis, myocarditis, and pericarditis. When required, corticosteroid therapy is initiated with 60 mg of prednisone equivalent per day given orally or intravenously for 2 to 3 days, and then tapered over a period of 1 to 2 weeks.

Therapy of other causes of mono syndrome

The mono-like symptoms of acute infections with CMV, toxoplasma, HIV, rubella, and the hepatitis viruses are usually self-limiting. Additional details about the individual case are sought to determine whether interventions, other than supportive care, should be applied. Pregnancy and cellular immunodeficiency are important factors to consider in the decision. Profound cellular

immune deficiency usually requires use of antimicrobial treatment for acute CMV (see Chapter 182, Cytomegalovirus) and toxoplasma (see Chapter 199, *Toxoplasma*) infections. Primary CMV, toxoplasma, and rubella infections in pregnancy pose a risk to the baby (TORCH syndrome), warranting a consultation with an obstetrician with expertise in this area. Primary toxoplasmosis of pregnancy necessitates antimicrobial therapy (see Chapter 199, *Toxoplasma*). Antiretroviral therapy given during pregnancy can substantially reduce perinatal HIV transmission, but its use requires knowledge of the attendant toxicities and risks (see Chapter 95, Pregnancy and the puerperium: infectious risks). Immediate antiretroviral therapy should be considered in persons with acute HIV infection (see Chapter 99, HIV-1 infection: antiretroviral therapy).

PREVENTION

There is not a vaccine for prevention of EBV infection or disease. Hospitalized patients with IM need not be isolated. Asymptomatic viral shedding long after the acute illness remains a potential risk for EBV transmission. Restricting intimate contact can decrease EBV transmission but is not practical unless the EBV infection would be intolerable.

186. Hantavirus cardiopulmonary syndrome in the Americas

Gregory J. Mertz and Michelle J. Iandiorio

INTRODUCTION

Hantavirus cardiopulmonary syndrome (HCPS) is a viral zoonosis that may result in cardiogenic shock and respiratory failure with significant associated mortality. Hantavirus infection has been identified throughout much of North, Central, and South America. In the United States 586 cases of HCPS have been reported through December 2012 with a case-fatality rate of 35%. Half of these cases have been in the Four Corners area in the southwest. The incidence is even greater in South America, particularly in Argentina, Brazil, Chile, and Paraguay. In Chile alone, 795 cases have been reported through December 2012, with a case-fatality rate of 35%.

VIROLOGY

HCPS is caused by an infection with a hantavirus. There have been over 20 New World hantaviruses identified since their discovery in 1993. The New World hantaviruses differ from the Old World hantaviruses that cause hemorrhagic fever with renal syndrome (HFRS) and are found primarily in Asia and Europe. The most common hantavirus causing HCPS in Canada and the United States is Sin Nombre virus (SNV). Other hantaviruses that cause significant disease in Central and South America include Andes virus (ANDV) in Chile and Argentina, Choclo virus in Panama, and Laguna Negra virus in Paraguay. The hantaviruses are small single-stranded negative-sense RNA viruses that belong to the family Bunyaviridae, a family known to include other viruses that cause significant zoonotic illnesses.

EPIDEMIOLOGY

Hantavirus infection is spread to humans by a rodent reservoir. The primary rodent responsible for human transmission in North America is the deer mouse, *Peromyscus maniculatus*. These asymptomatic rodent hosts shed the virus in urine, feces, and saliva. Humans are thought to be infected when the aerosolized excreta are inhaled. People are exposed most often when they are cleaning enclosed areas where dried excreta are disturbed. Exposure through rodent bite has also been identified. Human-to-human transmission has only been documented with ANDV infections in Chile and Argentina. In Chile, approximately one-third of cases occur in household clusters, and most secondary cases in these clusters result from person-to-person transmission. In a recent prospective study of household contacts of patients with HCPS in Chile, Ferrés *et al*. reported a significantly higher risk of the development of HCPS in sex partners and other close household contacts as compared to members of the household who slept in different rooms and denied sexual contact.

CLINICAL SYNDROME

Most cases involve an individual with a prolonged exposure history, so it is often difficult to determine the exact incubation period. In a small series from Chile where individuals had brief periods of exposure to high-risk areas, the median incubation period between exposure and onset of clinical disease was 18 days, with a range of 11 to 32 days. Clinical disease begins with a febrile prodrome consisting of 2 days to a week of fevers and myalgias, often with associated headache, backache, abdominal pain, nausea, and diarrhea. After several days with nonspecific prodromal symptoms, the cardiopulmonary phase starts abruptly with cough and dyspnea. This stage of disease may be mild, requiring only supplemental oxygen, or severe, causing rapid pulmonary edema and respiratory failure requiring mechanical ventilation. Severe disease is also characterized by cardiogenic shock, hemoconcentration, and lactic acidosis that may result in profound shock, cardiac arrhythmias, and death. The cardiopulmonary phase

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

usually lasts 2 to 4 days. If the patient survives the cardiopulmonary phase, the patient will proceed into the diuretic phase with subsequent resolution of the pulmonary edema. Convalescence is prolonged and may include weakness, fatigue, and impaired exercise tolerance with abnormal diffusion capacity.

DIAGNOSIS

Early presumptive diagnosis is critical because patients often progress to shock and death before definitive diagnosis can be made. The appropriate exposure history is helpful but not always present. Clinical diagnosis during the prodrome is difficult as there may be no cough, a normal chest radiograph, and no lab abnormalities except for thrombocytopenia.

A definitive diagnosis of HCPS is based on serologic testing for hantavirus-specific immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies. These antibodies become positive during the febrile prodrome, but the clinician must have a high degree of suspicion to order the tests. In addition, the serologic test results are usually not available for at least 8 to 24 hours.

The serologic tests available in the United States include the enzyme-linked immunosorbent assay (ELISA), which is available at many state health departments via the Centers for Disease Control and Prevention (CDC), and a strip immunoblot assay (SIA). An acute infection is characterized by a positive IgM and negative IgG or a 4-fold rise in IgG titers. Nested reverse transcription–polymerase chain reaction (RT–PCR) can detect hantavirus RNA in peripheral mononuclear cells and in serum but is limited to research laboratories. Hantavirus RNA has been detected in peripheral blood cells up to 2 weeks before the onset of symptoms or detection of antihantavirus antibodies and for up to 13 weeks after onset of illness. Postmortem diagnosis may also be established by detection of hantavirus antigens in tissue by immunohistochemistry.

A presumptive diagnosis can generally be made at the onset of the cardiopulmonary phase on the basis of the clinical presentation, radiologic findings, and a review of the peripheral blood smear. Characteristic hemodynamic findings may also be helpful in establishing a diagnosis. The chest radiograph will show findings consistent with pulmonary edema, including bilateral pulmonary infiltrates, Kerley B lines, indistinct hilar borders, and peribronchial cuffing, which progress rapidly over the next 12 hours. A peripheral blood smear should be evaluated by an experienced pathologist. Clues to the diagnosis include the following: thrombocytopenia (platelet count $\leq 150 \times 10^3$ mm^3), left-shift (presence of myeloblasts), a lack of toxic granulation in neutrophils, hemoconcentration (hematocrit >50 in men and >48 in women), and >10% immunoblasts among lymphocytes. When evaluating a patient in whom there is a high clinical suspicion of HCPS, presence of four of five of these peripheral blood criteria has a sensitivity of 96% and a specificity of 99%. Unfortunately, these criteria apply only once the patient is already in the cardiopulmonary phase and therefore cannot be used for diagnosis in the prodromal stage. Other clinical findings in the cardiopulmonary phase include a low cardiac index associated with a high systemic vascular resistance, in contrast to parameters found in septic shock. Alanine aminotransferase and aspartate aminotransferase levels, while normal during the prodrome, are generally abnormal at the onset of the cardiopulmonary phase and often peak during the diuretic phase as the patient is improving.

TREATMENT

When there is clinical suspicion of HCPS, the patient should be transported to a facility in which cardiovascular and ventilatory support is available. Volume resuscitation should be avoided, as this can exacerbate the pulmonary edema. Supplemental oxygen should be provided, including ventilatory support if necessary. A pulmonary artery catheter should be placed for the monitoring of cardiac index and systemic vascular resistance. Early use of pressors should be utilized when appropriate. Norepinephrine is preferred as the initial agent in patients with hypotension, whereas dobutamine is preferred when there is a decrease in cardiac output but blood pressure is maintained. High-dose norepinephrine can be used in addition to dobutamine, if necessary.

If extracorporeal membrane oxygenation (ECMO) is available, the patient should be evaluated by the critical care and ECMO team, including cardiothoracic or vascular surgery, as soon as a presumptive diagnosis is made. In patients who are continuing to deteriorate despite full ventilatory and pressor support, ECMO should be considered. The University of New Mexico Hospital (UNMH) in Albuquerque, New Mexico, has the most experience with the use of ECMO for this condition. The criteria for the use of ECMO at this institution include a cardiac index less than

2.3 L/min/m^2, PaO_2/FiO_2 of less than 50, and a lack of response to conventional support. Exclusion criteria include age over 70 years, severe pre-existing comorbid disease, and neurologic impairment. Of the 51 patients treated with ECMO at UNMH between 1994 and 2010, 34 (67%) survived to discharge. Furthermore, survival was 80% among the 25 patients treated between 2003 and 2010 who underwent elective insertion of arterial and venous vascular sheaths once a presumptive or definitive diagnosis of HCPS was established, were intubated nearly concurrently with vascular sheath placement, and then placed on ECMO if decompensation occurred.

There is no approved therapy for the treatment of HCPS. Intravenous ribavirin did not lead to any survival benefit in a placebo-controlled trial in North America, and treatment with high-dose methylprednisolone was ineffective in a randomized, placebo-controlled trial in patients with HCPS in Chile. Promising preliminary data have been reported from an open, phase I trial of treatment with fresh frozen plasma containing anti-ANDV neutralizing antibodies recently conducted in Chile. While promising, these data remain unpublished, and there are no neutralizing antibody products available at this time for evaluation in further clinical trials or clinical use for any of the major pathogenic hantaviruses in North or South America.

187. Herpes simplex viruses 1 and 2

Richard J. Whitley

THE VIRUS

Herpesviruses are generally defined as large enveloped virions with an icosapentahedral nucleocapsid consisting of 162 capsomeres arranged around a double-stranded DNA core. The two antigenically distinct types of herpes simplex virus (HSV) are HSV-1 and HSV-2. Considerable homology exists between the HSV-1 and HSV-2 genomes, with most of the polypeptides specified by one viral type being antigenically related to polypeptides of the other viral type. Although this results in considerable cross-reactivity between the HSV-1 and HSV-2, glycoproteins G (gG) are unique antigenic determinants that allow for differentiation between these two viruses (e.g., gG-1 and gG-2). Surrounding the viral genome and nucleocapsid is a tightly adherent membrane known as the *tegument*. A lipid envelope containing the viral glycoproteins loosely surrounds the tegument.

PATHOLOGY AND PATHOGENESIS

Cutaneous HSV infection causes ballooning of infected epithelial cells, with nuclear degeneration, loss of intact cellular membranes, and the formation of multinucleated giant cells. Ultimately, cells lyse and release clear fluid containing large quantities of virus, with subsequent accumulation of cellular debris and inflammatory cells between the epidermal and dermal layers. Multinucleated giant cells are usually present at the base of the vesicle. An intense inflammatory response extends from the base of the vesicle into the dermis, producing the erythema that classically surrounds a cluster of HSV vesicles. As the lesions heal, vesicular fluid becomes purulent as more inflammatory cells are recruited to the site of infection. Scab formation then follows. Scarring is uncommon.

When infection involves mucous membranes, shallow ulcers are more common than vesicles because of rapid rupture of the very thin cornified epithelium present at mucosal sites. Nevertheless, the histopathologic findings of mucosal lesions are similar to those of skin lesions.

EPIDEMIOLOGY

Although HSV-1 is found most commonly in the oropharynx, it is an increasingly common cause of first episode genital herpes, accounting for at least half of all new infections, and can infect any organ system. Factors that influence the frequency of primary HSV-1 infection include geographic location, socioeconomic status, and age. Throughout childhood and adolescence, African Americans maintain approximately twice the prevalence of HSV-1 antibodies as white children, with 40% of African American children being seropositive for HSV-1 by 5 years of age. By the age of 60 years, however, both African Americans and whites have a similarly high prevalence of HSV-1 antibody (up to 90%).

Recurrences of herpes labialis have been associated with physical or emotional stress, fever, exposure to ultraviolet light, tissue damage, and immune suppression. As with primary infections, recurrent disease may occur in the absence of clinical symptoms. At any given time, 1% of healthy children and 1% to 5% of normal adults asymptomatically excrete HSV-1, as demonstrated by viral culture. Recent studies employing polymerase chain reaction (PCR) suggest that these numbers may be at least 3-fold higher.

HSV-2 causes 75% to 80% of the cases of recurrent genital HSV infections in the United States. As would be expected, antibodies to this virus are rarely found before the onset of sexual activity. Among adolescents and adults, factors that correlate with seroprevalence for HSV-2 include sex (higher for women than for men), race (higher for African Americans than for whites), marital status (higher for persons previously married than for single or married persons), number of sexual partners (increasing likelihood with

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

Figure 187.1 Herpes simplex gingivostomatitis.

Figure 187.2 Recurrent herpes simplex labialis.

increasing number of partners), and income level (higher probability for those persons earning lesser amounts of money).

The propensity for recurrence of genital HSV infection depends on a variety of factors, including sex (more common in men), viral type (more common with HSV-2), and the presence and titer of neutralizing antibodies (more common in the presence of high neutralizing antibody titers). Overall, 60% to 90% of patients with primary genital HSV-2 infection will experience clinically apparent recurrence of infection.

CLINICAL MANIFESTATIONS

Oropharyngeal HSV infection

Primary oropharyngeal infection with HSV-1 occurs most commonly in young children between 1 and 3 years of age. It is usually asymptomatic. The incubation period ranges from 2 to 12 days, with an average of 4 days. Symptomatic disease is characterized by fever to 104°F, oral lesions, sore throat, fetor oris, anorexia, cervical adenopathy, and mucosal edema. Oral lesions initially are vesicular but rapidly rupture, leaving 1- to 3-mm shallow gray-white ulcers on erythematous bases. These lesions are distributed on the hard palate, the anterior portion of the tongue, along the gingiva, and around the lips (Figure 187.1). In addition, the lesions may extend down the chin and neck due to drooling. Total duration of illness is 10 to 21 days.

Primary infection in young adults has been associated with pharyngitis and often a mononucleosis-like syndrome. In such patients, ulcerative lesions on erythematous bases frequently are apparent on the tonsils.

Primary gingivostomatitis results in viral shedding in oral secretions for an average of 7 to 10 days. Virus is also shed in the stool.

Recurrent orolabial HSV lesions are often preceded by a prodrome of pain, burning, tingling, or itching. These symptoms generally last for less than 6 hours, followed within 24 to 48 hours by the appearance of painful vesicles, typically at the vermillion border of the lip (Figure 187.2). Lesions usually crust within 3 to 4 days, and healing is complete within 8 to 10 days. Recurrences occur only rarely in the mouth or on facial skin of immunocompetent patients.

Genital HSV infection

Genital HSV disease (Figure 187.3) is usually acquired by sexual contact with an infected partner. Historically, virtually all cases of genital herpes were caused by HSV-2 but, with changing sexual behavior, at least 50% of cases today are the consequence of HSV-1. The incubation period of primary disease ranges from 2 to 12 days. Lesions persist for an average of 21 days. In 70% of patients, primary infections are associated with fever, malaise, myalgias, inguinal adenopathy, and other signs and symptoms of systemic illness. Complications include extragenital lesions, aseptic meningitis, and sacral autonomic nervous system dysfunction with associated urinary retention. Women tend to experience more severe primary infections and are more likely to develop complications.

Figure 187.3 Genital HSV infection in woman (primary infection) and man (recurrence).

In males, primary genital HSV infection usually manifests as a cluster of vesicular lesions on erythematous bases on the glans or shaft of the penis. In females, primary genital HSV lesions usually involve the vulva bilaterally. Concomitant HSV cervicitis occurs in 90% of women with primary HSV-2 infection of the external genitalia. In women, the lesions rapidly ulcerate and become covered with a gray-white exudate. Lesions may be exquisitely painful. Recurrent genital HSV-2 infection can be either symptomatic or asymptomatic. A prodrome of itching, burning, tingling, or tenderness may be noted several hours before a recurrence. The duration of disease is shorter during recurrent infection (7 to 10 days), and fewer lesions are present. In men, lesions usually appear on the glans, or shaft, of the penis. In women, lesions occur most commonly on the labia minora, labia majora, and perineum. Cervical excretion of HSV occurs in 10% of women with recurrent genital lesions. Systemic symptoms are uncommon in recurrent genital HSV disease. Genital HSV-1 infections are much less likely to recur.

Transmission usually occurs in the absence of clinical symptoms, and occurs more often from men to women. Importantly, HSV-2 seropositive but asymptomatic individuals are just as likely to transmit infection as those who are symptomatic.

Other primary HSV skin infections

Alteration in the barrier properties of skin, as occurs in atopic dermatitis, can result in localized HSV skin infection (eczema herpeticum). Most cases resolve over a 7- to 9-day period without specific therapy. Localized cutaneous HSV infection after trauma is known as herpes gladitorium (wrestler's herpes or traumatic herpes).

HSV infection of the digits results in herpetic whitlow. Such lesions may be the result of autoinoculation, as in the case of infants, or exogenous exposure, as occurs among medical and dental personnel who fail to wear gloves.

Ocular HSV infection

Herpetic infection of the eye usually presents as either a blepharitis or a follicular conjunctivitis. As disease progresses, branching dendritic lesions develop. Symptoms include severe photophobia, tearing, chemosis, blurred vision, and preauricular lymphadenopathy. An ophthalmologist should always be involved in the care of such patients.

Central nervous system HSV infection

Central nervous system (CNS) signs and symptoms of HSV disease can begin suddenly or can follow a 1- to 7-day period of nonspecific

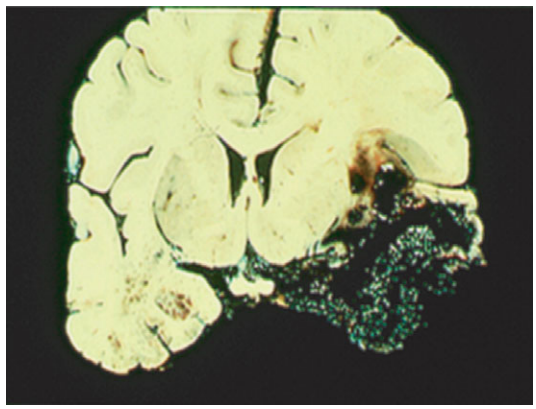

Figure 187.4 Brain with temporal lobe necrosis.

influenza-like symptoms. Prominent CNS features include headache, fever, altered consciousness, and focal neurologic findings such as focal seizures. Clinical signs and symptoms may reflect the characteristic frontal and temporal lobe localization, such as memory loss, anosmia, olfactory hallucinations, speech disorders, and behavioral disturbances, often accompanied pathologically by focal necrosis (Figure 187.4).

Neonatal HSV infections

Neonatal HSV infection can be classified as (1) disease localized to the skin, eye, and/or mouth (SEM) (45% of cases); (2) encephalitis, with or without SEM involvement (30% of cases); and (3) disseminated infection that involves multiple organs, including the CNS, lung, gastrointestinal tract, liver, adrenals, skin, eye, and/or mouth (25% of cases). Infants with disseminated and SEM disease usually present for medical attention within the first 2 weeks of life, whereas infants with disease localized to the CNS usually present between the second and third weeks of life. Presenting signs and symptoms can include any combination of irritability, seizures (both focal and generalized), lethargy, tremors, poor feeding, temperature instability, bulging fontanelle, respiratory distress, jaundice, disseminated intravascular coagulopathy, shock, and cutaneous vesicles. It is important to note that >40% of infants with disseminated disease and >30% of infants with encephalitis will never have skin vesicles during the course of illness. Even in cases of SEM disease, almost 20% of neonates do not have skin lesions.

HSV in the immunocompromised host

Patients compromised by immunosuppressive therapy, underlying disease, or malnutrition are at increased risk for severe HSV infection. Disseminated disease may occur with widespread dermal, mucosal, and visceral involvement. Alternatively, disease may remain localized but persist for much longer periods of time than would be seen in immunocompetent hosts.

DIAGNOSIS

Type-specific serologic tests allow the distinction between HSV-1 and HSV-2. These tests can be utilized to determine those people at risk for infection or those previously infected but who remain unaware of their status. The diagnosis of HSV is best achieved by either the isolation of HSV by culture or the detection of viral DNA by PCR. If skin lesions are present, a scraping of the vesicles should be transferred in appropriate viral transport medium on ice to a diagnostic virology laboratory. Other sites from which virus may be isolated include the cerebrospinal fluid (CSF) but rarely, urine, throat, nasopharynx, conjunctivae, and duodenum. The presence of intranuclear inclusions and multinucleated giant cells on a Tzanck prep are indicative of, but not diagnostic for, HSV infection. The application of PCR to lesion scrapings is becoming increasingly valuable for proof of HSV, especially late in the course of vesicular evolution.

In HSV encephalitis, CSF findings are variable but often include a moderate pleocytosis with a predominance of mononuclear cells, elevated protein level, and normal or slightly decreased glucose. The electroencephalogram (EEG) generally localizes spike and slow wave activity to the temporal lobe, even when obtained very early in the disease course. Computed tomography (CT) of the brain may initially be normal or reveal only edema, but as the disease progresses can demonstrate temporal lobe involvement as well. Detection of HSV DNA in the CSF by PCR has become the diagnostic method of choice; however, it must be performed only by a reliable laboratory.

TREATMENT

Herpes labialis

The treatments of choice for herpes labialis are acyclovir, valacyclovir, or famciclovir. Orally administered acyclovir at a dosage of 400 mg five

Table 187.1 Antiviral therapy in herpes simplex virus (HSV) infections

Type of infection	Drug	Route and dosage[a]	Comments
Genital HSV	Acyclovir	200 mg PO 5×/d ×10 d	Preferred route in normal host
Initial episode		5 mg/kg IV q8h ×5 d	Reserved for severe cases
Recurrent episode	Valacyclovir	1 g PO BID ×10 d	
Suppression	Famciclovir	250 mg PO TID ×10 d	
	Acyclovir	200 mg PO 5×/d ×5 d	
	Valacyclovir	500 mg PO BID × 3 d	
	Famciclovir	1 g PO BID × 1 d	
	Acyclovir	400 mg PO BID	
	Valacyclovir	500 mg or 1 g PO qd	
	Famciclovir	250 mg PO BID	
Herpes labialis	Acyclovir	400 mg PO 5×/d × 5 d	
	Valacyclovir	2 g PO BID for 1 d, taken about 12 h apart	
	Famciclovir	1500 mg administered once	
Mucocutaneous HSV in immunocompromised patient	Acyclovir	200–400 mg PO 5×/d ×10 d	
		5–10 mg/kg IV q8h ×7–10 d	
	Valacyclovir	500 mg BID PO	
	Famciclovir	500 mg TID PO	
HSV encephalitis	Acyclovir	10–15 mg/kg IV q8h ×14–21 d	
Neonatal HSV	Acyclovir	20 mg/kg IV q8h ×14–21 d	
Suppression		250 mg/m^2 q8h × 6 mo	
Herpetic conjunctivitis	Trifluridine	1 drop q2h while awake × 7–14 d	Alternative: vidarabine ointment

[a] The dosages are for adults with normal renal function unless otherwise noted.

Adapted from Workowski KA, Berman S; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2010. *MMWR Recomm Rep.* 2010;59(RR-12):1–110.

times daily for 5 days reduces the duration of pain and time to the loss of crusts by about one-third, but only if treatment is started during the prodromal or erythematous stage of recurrent infection. Similar benefit is achieved with valacyclovir (2 g twice daily for 1 day, taken about 12 hours apart). Clinical benefit is achieved only if therapy is initiated very early after recurrence. Recently, 1-day therapy with famciclovir was approved by the US Food and Drug Administration. When administered during prodrome, 1500 mg administered once accelerates healing.

Topical therapies provide little benefit in the management of herpes labialis. Although these therapies are licensed, this author does not recommend their use. Similarly, data do not support the use of long-term suppressive treatment with acyclovir for the prevention of herpes labialis.

Genital herpes

The treatments of choice include acyclovir (oral or intravenous), valacyclovir (oral), or famciclovir (oral). Although topical acyclovir is approved for treatment of genital herpes, it is not recommended. Treatment of primary genital herpes in the normal host decreases the duration of symptoms, viral shedding, and time to healing of lesions (Table 187.1). However, neither systemic nor topical treatment of primary HSV lesions reduces the frequency or severity of recurrences. Episodic administration of oral or topical acyclovir for the treatment of recurrent genital HSV lesions provides only a modest benefit, with duration of lesions being shortened at most by 1 to 2 days. However, daily administration of oral acyclovir, valacyclovir, or famciclovir can effectively suppress recurrences of genital herpes in 60% to 90% of patients. Importantly, suppressive therapy does not totally prevent reactivation; thus, transmission can occur, albeit less frequently. Treatment should be interrupted approximately yearly to reassess the need for continued suppression.

Both valacyclovir and famciclovir are now licensed for the treatment and suppression of genital HSV. There is a pharmacokinetic advantage with these medications. For recurrent infection, valacyclovir is usually administered at 500 mg twice daily for 3 days, and famciclovir is administered at 1 g twice daily for 1 day.

The transmission of genital HSV infection can be decreased by administration of valacyclovir (500 mg once daily) to the infected partner.

Mucocutaneous HSV infections in immunocompromised patients

In immunocompromised patients, the three aforementioned antiviral drugs all diminish the duration of viral shedding, as well as substantially accelerate the time to cessation of pain and to total healing of HSV lesions. In addition, prophylactic administration of these drugs to such patients significantly reduces the incidence of symptomatic HSV infection (see Table 187.1).

Herpes simplex keratoconjunctivitis

Idoxuridine (Stoxil), trifluridine (Viroptic), and vidarabine ophthalmic drops all are effective and licensed for treatment of HSV keratitis. Trifluridine is the most efficacious and the easiest to administer, and as such is the drug of choice for HSV ocular disease (see Table 187.1).

Herpes simplex encephalitis

In patients with HSV encephalitis, acyclovir administration greatly reduces mortality and has a modest impact on morbidity. Dosage and length of therapy are shown in Table 187.1. Outcome is more favorable when therapy is instituted early in the disease course.

Neonatal HSV infections

Intravenous acyclovir is the drug of choice in the treatment of neonatal HSV infection (see Table 187.1). Therapy is most efficacious if instituted early in the course of illness. Because of the exceptional safety profile of acyclovir, an intravenous dosage of 60 mg/kg/day divided every 8 hours should be given. Duration of therapy is 14 to 21 days. Suppressive therapy with acyclovir is indicated after completion of intravenous therapy. The dosage is 250 mg/m^2 every 8 hours for 6 months.

Infants with ocular involvement caused by HSV should receive topical antiviral medication in addition to parenteral therapy. Trifluridine is the treatment of choice for ocular HSV infection in the neonate (see Table 187.1).

188. Human herpesviruses 6, 7, 8

Ruth M. Greenblatt

Human herpesviruses (HHV) 6, 7, and 8 are capsid-enclosed DNA viruses that produce lytic and latent infection of lymphocytes and other cell types. Reactivation of latent infection occurs intermittently, with replication of virus in tissues and shedding in various secretions. HHV-6, HHV-7, and HHV-8 constitute a diverse group in terms of their biology, pathogenesis, and the diseases they produce; HHV-6 and HHV-7 are able to infect a broader array of cell types than HHV-8. Clinical presentation ranges from asymptomatic infection or mild illnesses, such as febrile exanthems, in the case of HHV-6 and HHV-7, extending to life-threatening disease in the immune compromised host. Selected clinical and virologic characteristics are summarized in Table 188.1 and limited antiviral treatment information is presented in Table 188.2.

HUMAN HERPESVIRUS 6

HHV-6 is a member of the *Betaherpesvirinae* group of the genus *Roseolovirus*, of which cytomegalovirus (CMV) was the only previously recognized human pathogen. HHV-6 consists of two related variants, HHV-6A and HHV-6B, that have 90% DNA homology and cannot be distinguished by serologic tests, but have distinctive molecular, cell culture, and clinical features. Infection is ubiquitous; 70% to 100% of adults worldwide have serologic evidence of HHV-6 infection. Infection follows a 2-week incubation period and most often occurs between the ages of 6 and 15 months.

Shedding and tissue tropism

HHV-6B is shed in saliva, which is an important vehicle of transmission (perhaps most often from mother to child). The virus is not found in breast milk. After primary infection, viral replication occurs in salivary glands and recurs during periodic episodes of reactivation and shedding, which decrease in frequency over time. Both variants are lymphotropic; primarily infect CD4-positive T cells; the A variant also infects CD8 cells. HHV-6 infects other lymphocytes, monocytes, macrophages, and epithelial and endothelial cells utilizing the CD46 molecule as its receptor. The virus is highly neurotropic with a central nervous system (CNS) site of latency. HHV-6 is unique among human herpesviruses in that its DNA can integrate into specific locations on chromosomes 1, 17, and 22. HHV-6 DNA integration into germ cells can result in inheritance of HHV-6 genetic elements and when it occurs, is associated with persistent high-level viremia. High-level viremia suggestive of chromosomal integration is uncommon but not rare; it was reported in 3% of blood donors in a recent British study but the prevalence may vary significantly by population group. One percent of newborns have congenital HHV-6 infection, the majority of instances of which occur in the setting of maternal chromosomal integration. Unlike CMV, transplacental transmission of HHV-6 only rarely results in clinical sequelae.

Infection in immunocompetent hosts

When detected, primary infection with HHV-6 is associated with fever $\geq 40^{\circ}C$, lasts 3 to 7 days, and then suddenly resolves. Infection with HHV-6B is characterized by fever followed by a maculopapular rash (exanthema subitum [ES] or roseola infantum or sixth disease) on the trunk, face, and neck; HHV-6 is a leading cause of skin rash and fever in children under 2 years of age. Malaise, otitis media, and gastrointestinal and respiratory symptoms are also common. It is estimated that HHV-6 may account for 20% to 25% of all emergency room visits for children 6 to 12 months of age and one-third of all febrile seizures in children <2 years of age in the United States. Encephalomeningitis is a rare complication; both HHV-6 variants can be recovered from cerebrospinal fluid (CSF), though the "A" variant is thought to be more neurotropic.

Table 188.1 Clinical features of human herpesviruses 6, 7, and 8

Virus	Age of first infection	Sites of shedding	Unique attribute	Clinical features of primary infection	Clinical features of infection in compromised hosts
HHV-6A	Most before 2 years	Serum, CSF	Chromosomal integration and germ cell transmission occurs	Not known	? pneumonitis, ? disseminated infections
HHV-6B	Most before 2 years, congenital and perinatal transmission is possible	Saliva, cervical secretions, stool, serum	Chromosomal integration and germ cell transmission occurs and is associated with persistent high-grade viremia	Pityriasis rosea, exanthem subitum, fever, febrile seizures, respiratory and GI symptoms	Pneumonitis, hepatitis, hemorrhagic cystitis, colitis, bronchiolitis obliterans, encephalitis, allograft rejection, suppression of bone marrow engraftment, retinitis, role in GVHD, optic neuritis, hemophagocytosis, dissemination, rash
HHV-7	Early childhood	Saliva, breast milk		Less frequent cause of exanthem subitum and other exanthems	Unknown
HHV-8	Childhood to puberty	Saliva, semen (rare)	Cancer-producing virus	Most often asymptomatic, febrile illness of infancy	Kaposi's sarcoma, multicentric Castleman's disease, body cavity-based lymphoma

Abbreviations: CSF = cerebrospinal fluid; GI = gastrointestinal; GVHD = graft-versus-host disease.

Table 188.2 Summary of in-vivo and in-vitro information regarding antiviral treatment of HHV-6, HHV-7, and HHV-8

Virus	Treatment indication	Drug	Comment
HHV-6B	Treatment of documented (direct detection of virus) bone marrow, lung, brain infection in transplant recipient	Ganciclovir, foscarnet, cidofovir	No proven efficacy in clinical trials, CMV dosing presumed to be required
HHV-7	None known	None known	
HHV-8	KS, MCD in AIDS patient KS in solid organ transplant recipient	1. cART regimen 2. Cidofovir, or ganciclovir, or foscarnet Withdraw as much immunosuppressive therapy as possible	Potent antiretroviral combination treatment CMV dosing, duration not known Proven efficacy Presumed CMV dosing, no clinical data, theoretical efficacy at best

Abbreviations: CMV = cytomegalovirus; KS = Kaposi's sarcoma; MCD = multicentric Castleman's disease; AIDS = acquired immunodeficiency syndrome; cART = complete antiretroviral therapy.

As in many other viral illnesses, the severe complications are more common in adults with primary infection; these include a mononucleosis-like syndrome, hepatitis, hemophagocytosis, thrombocytopenia, encephalitis, and/or fatal dissemination. HHV-6 may influence the occurrence of demyelinating diseases such as multiple sclerosis and Guillain–Barré syndrome, but a causal role has not been proven and research findings are often contradictory.

Infection in immunocompromised hosts

Active HHV-6B replication is frequently detected in immunocompromised hosts, such as bone marrow and solid organ transplant recipients. Most infections are identified 2 to 4 weeks post-transplantation. Serious infections can occur with a pattern that mimics CMV, including pneumonitis, colitis, hemorrhagic cystitis, encephalitis (most often involving the temporal lobe), hepatitis, bone marrow suppression, and graft-versus-host disease. HHV-6 contributes to the frequent occurrence of skin rash after bone marrow grafting and lesion histology can demonstrate lymphocytic basophilic inclusions and viral DNA. HHV-6 is associated with bronchiolitis obliterans among lung transplant recipients, and linked with eventual graft failure. HHV-6 activity may occur concurrently with CMV or HHV-7, making distinction of the clinical manifestations due to each virus difficult. Viremia may be particularly common after cord blood grafts. The intensity of HHV-6 viremia is related to the

occurrence of clinical manifestations and graft-versus-host disease in allogeneic bone marrow transplant recipients. Similarly, extent of viremia is linked to graft failure after solid organ transplantation.

HHV-6 can function as an opportunistic pathogen in acquired immunodeficiency syndrome (AIDS) patients with reported cases of encephalitis, pneumonitis, and retinitis. HHV-6 or-7 reactivation has been associated with DRESS syndrome (drug reaction with eosinophilia and systemic symptoms) which may respond to antiherpes treatment, though definitive studies have not been performed. As is the case for CMV, combination antiretroviral therapy (cART) appears to have reduced the incidence of serious HHV-6 infections in AIDS.

Detection of infection

The very high prevalence of infection, intermittent reactivation, and the occurrence of chromosomal integration must be considered in the interpretation of diagnostic tests for HHV-6; detection of virus does not necessarily indicate disease. Viral culture from peripheral blood mononuclear cells may be the gold standard for viral detection but it is not routinely available. Detection of HHV-6 DNA in either cellular or acellular specimens using polymerase chain reaction (PCR) is suggestive of active HHV-6 replication and occurs in children with ES and a variety of immunocompromised individuals. In classic childhood ES, etiologic diagnosis is seldom necessary. Immunohistochemistry can detect cells with active infection in biopsy or cytologic specimens. Serologic tests include indirect immunofluorescence assay (IFA), anticomplement immunofluorescence assay, competitive radioimmunoassay, neutralization, and enzyme immunoassays (EIA). The EIA tests are more easily quantified and are less subjective. Primary infection can be demonstrated by serologic conversion in children and adults or with the presence of immunoglobulin (Ig)M in children. The presence of IgM in adults may indicate either primary infection or reactivation from latency. A 4-fold increase in serum IgG by IFA or a 1.6-fold increase by EIA indicates recent infection.

Treatment of HHV-6 infection

In culture, gancyclovir, cidofovir, and foscarnet are active against both HHV-6 variants. Case reports describe clinical responses to gancyclovir, cidofovir, or foscarnet in transplant recipients with encephalitis, though treatment failures are also reported. Treatment is recommended for virologically confirmed infection in the setting of post-transplant bone marrow suppression, encephalitis, or pneumonitis. Analogous to CMV, bone marrow transplant recipients who receive high-dose acyclovir, despite lack of efficacy in vitro, appear to have fewer HHV-6 infections. Reduction in the intensity of immunosuppression is recommended when possible. Immunotherapies, such as transfer of HHV-6-specific T cells may, in the future, prove useful in life-threatening infections among bone marrow transplant recipients.

HUMAN HERPESVIRUS 7

HHV-7 is similar in terms of morphology and genome sequence to HHV-6; the viruses resemble each other more than CMV. HHV-7 is also a member of the *Betaherpesvirinae* group, genus *Roseolovirus*, infects CD4-positive T lymphocytes, and produces latent infection. Primary infection occurs during childhood, and is probably most often asymptomatic. Some evidence indicates that asymmetric periflexural exanthem (APE), a unilateral maculopapular eruption mostly of children, is associated with HHV-7 infection. Cross-reactivity between HHV-6 and HHV-7 in some assay systems may have complicated early studies of the viruses. Infection is ubiquitous; serum antibodies can be identified in >85% of adults. Salivary shedding occurs even more frequently than in the case of HHV-6 (can be found in saliva from 75% of adults) and exposure to oral secretions is likely the major mode of transmission. The virus can be detected in breast milk, CSF, cervical tissue, and peripheral blood lymphocytes. Congenital infection is rare, if it occurs at all.

HHV-7 infrequently causes ES; far less often than does HHV-6B. Other febrile illnesses of childhood have been reported in association with development of serum antibodies to HHV-7. The detection of HHV-7 DNA in blood from transplant recipients is reported variably, and the role of this virus in post-transplant morbidity is not clear. While HHV-7-related disease in transplant recipients is considered rare, the virus has been implicated in fever, rash, bone marrow suppression, and organ involvement. Few research data are available to guide treatment, but reduction in immune suppression, or foscarnet or cidofovir are recommended for clinically evident disease.

Table 188.3 Clinical characteristics of conditions associated with HHV-8 infection

Condition	Setting	Clinical characteristics
Classic KS	A rare condition seen among elderly men of Mediterranean or Ashkenazi Jewish descent. No known environmental etiologic precipitator	Indolent condition that typically involves lower extremities, slowly progressive, primarily cutaneous, often not cause of death
Endemic KS	A relatively common cause of cancer (or a cancer-like condition) in children and adults residing in central Africa. No known environmental etiologic precipitator	Variable from mild (like classic) to locally aggressive disease
Iatrogenic KS	Seen in solid organ transplant recipients and other recipients of medication-induced immunologic suppression	Aggressive condition that often improves or resolves with withdrawal of immunosuppressive therapy, and may recur with reinstitution
AIDS KS	AIDS-defining illness in HIV-infected patients, most often homosexual men (in developed countries). One of the most common HIV-associated malignancies, the incidence is falling	Often aggressive condition that progressively involves metastatic mucosal or cutaneous foci (often the mouth, face, and genitalia), and then may extend to lymphatic, pulmonary, and gastrointestinal tract disease. Paradoxical worsening may occur after immune reconstitution with antiretroviral therapy
Multicentric Castleman's disease (MCD)	HHV-8-associated MCD is a distinct entity characterized by systemic inflammation, episodic flares that are potentially fatal. Incidence has not declined in era of effective HIV treatment	Intermittent symptoms of systemic inflammation: fever, fatigue, loss of appetite, cough, nausea, diarrhea, and edema. Lymphadenopathy and splenomegaly are common. Flares are associated with anemia and thrombocytopenia, elevated C-reactive protein, hyponatremia, and hypoalbuminemia. May progress to non-Hodgkin's lymphoma
Body cavity-based lymphoma	Most common in AIDS patients, most cases reported in men, but occurs in women. Has been reported in recipients of solid organ transplants	Aggressive lymphoma which typically presents with ascites or pleural effusion and no solid tumor mass

HUMAN HERPESVIRUS 8

HHV-8 is a member of the *Gammaherpesvirinae* group with Epstein–Barr virus (EBV). In central Africa, a region in which Kaposi's sarcoma (KS) was common before the human immunodeficiency virus (HIV) epidemic, HHV-8 infection is a common cause of febrile illness in infants and may be associated with respiratory symptoms in some cases. In these areas the prevalence of HHV-8 infection increases with age, reaching 39% to 48% in adolescence. In immunocompromised hosts, particularly those with loss of T-cell function, primary HHV-8 infection may be associated with the transient development of KS and related conditions. In the absence of deficiencies of T-lymphocyte function, HHV-8 infection is clinically unremarkable. HHV-8 infects a variety of cell types, including B lymphocytes and vascular endothelial cells. Lytic and latent infections occur; relatively few viral gene products are expressed in latently infected cells. Lytic infection is characterized by the transcription of a wide array of viral genes, producing gene products with immunomodulatory functions that participate in the pathogenesis of HHV-8-related malignancies. A viral version of interleukin-6 (*v*IL-6) appears to play a particularly important role in the inflammatory nature of HHV-8-related malignancies. The clinical characteristics of conditions associated with HHV-8 infection are summarized in Table 188.3.

Kaposi's sarcoma

Moritz Kaposi first described classic KS in 1872 as a rare skin tumor seen primarily in elderly men of Mediterranean or Ashkenazi Jewish origin. While KS is somewhat unique as a malignancy by involving multiple types of cells, HHV-8 infection of its characteristic spindle cell, and a clear relationship between intensity of HHV-8 replication and risk of KS supports the conclusion that the virus is causative. The occurrence of KS is associated with impaired natural killer lymphocyte responses characterized by altered surface receptor expression; resolution of this immune impairment can result in clinical regression. Early KS lesions appear as faint red-violet or brown macules that increase in size, become papular, and can ulcerate. Typically, untreated KS evolves from skin to mucosal, lymphatics (often with lymphedema), and then internal organs. Genital and/or oral lesions are not uncommon.

The endemic or African form of KS was recognized in the early part of this century, and is confined to equatorial areas where, until the AIDS era, it accounted for up to 10% of all malignancies. In a 1990 study, the risk of KS was at least 20 000 times greater among AIDS patients than the general population and 300 times greater among AIDS patients than other immunosuppressed groups. AIDS KS is more prevalent among men who have sex with men than in other HIV exposure groups (such as injection drug users). AIDS KS has a variable course, which can range from isolated skin lesions to more aggressive disease with rapid dissemination. An immune reconstitution phenomenon, as occurs paradoxically with AIDS opportunistic infections, occurs with KS and is characterized by the onset of KS or worsening of existing KS lesions after initiation of cART. Generally cART can be continued through immune reconstitutional KS, but fatal disease has been reported, particularly in resource-poor settings. The incidence of KS among HIV-infected persons has greatly decreased among recipients of cART. An iatrogenic form of KS occurs primarily in solid organ transplant recipients and tends to be an aggressive illness with rapid dissemination, unless immunosuppressive therapies are discontinued or modified.

Multicentric Castleman's disease (MCD and MCD-associated plasmablastic lymphoma)

MCD is a rare lymphoproliferative condition involving B cells characterized by multicentric angiofollicular hyperplasia associated with fever, adenopathy, and splenomegaly. Several clinical variations exist; HHV-8-related MCD appears to be distinct from forms that are not linked to the virus, and almost always occurs with HIV infection. Contrasting with KS, the occurrence of MCD has not declined in the present era of potent antiretroviral treatment. HHV-8 DNA sequences are found in the polyclonal plasmacytoid cells within lymph nodes that are diagnostic for HHV-8-associated MCD. HHV-8 sequences of patients with MCD may have unique microRNA signatures which may contribute to viral pathogenesis. Survival with MCD is variable and the clinical course is remissive with severe flares that are associated with intensity of HHV-8 viremia. No standard therapy exists for HHV-8 MCD, though responses to antiretroviral and antiherpes drugs, cytotoxic chemotherapies, anti-CD20 monoclonal antibody (rituximab), and/or glucocorticoids do occur. MCD can transition to a large B-cell non-Hodgkin's lymphoma.

Primary effusion lymphomas (PEL) or body cavity-based lymphoma (BCBL)

This is a rare non-Hodgkin's lymphoma of B-cell origin occurring among persons with marked immunologic dysfunction, most commonly due to HIV infection. PEL presents as a neoplastic effusion of the pleural, pericardial, and peritoneal cavities in the absence of a solid tumor mass. PEL diagnoses require typical body cavity malignant effusions and the presence of HHV-8 and EBV; no other lymphomatous effusion expresses HHV-8. Solid lymphomas have been reported prior to and subsequent to PEL. In general, prognosis of PEL is poor, though some HIV-infected patients demonstrate improvement after initiation of cART. In addition, noncurative but significant responses have been reported after the intracavitary administration of cidofovir, an antiviral drug with broad efficacy.

Detection of infection

Standardized methods for detection of HHV-8 infections have not yet been established. Prevalence rates depend on testing method as well as the population being evaluated. DNA detection techniques such as PCR may be of limited value in studying the epidemiology of HHV-8 since infected tissue must be directly sampled and the technique is cumbersome and sensitive to laboratory error. Indirect IFA and EIA have been developed for the detection of antibodies to lytic and latent HHV-8 antigens. Antibody assays range from 80% to 98% sensitivity in KS patients (when compared with PCR). The pattern of reactivity to lytic versus latent antigens does not appear to impart much clinical information.

Epidemiology and modes of transmission

HHV-8 antibodies are highly prevalent among patients with KS and in homosexual men. The prevalence of serologic reactivity is also relatively high among persons in regions where KS was endemic prior to the AIDS epidemic. The prevalence of HHV-8 infections in various populations is summarized in Table 188.4. As is true of many herpes simplex virus infections and other sexually transmitted diseases (STDs), prevalence rates

Table 188.4 Estimated prevalence of HHV-8 infection in various populations

Population	% Prevalence[a]
Homosexual men in industrialized countries	21–67
Injection drug users in industrialized countries	5–50
HIV-uninfected heterosexual patients	<1–64
US women with HIV infection	4–15
Solid organ donors	4–10

[a] Prevalence rates depend on type of diagnostic test, are higher with lytic antigen.

tend to increase with age and incidence peaks during years of greatest sexual activity.

HHV-8 is likely transmitted via oral contact with infected saliva in a manner analogous to that of EBV. Among body fluids, HHV-8 is most often shed in oral sections. HHV-8 has a far lower prevalence rate and later age of infection than occurs with HHV-6, HHV-7, and EBV, infections in which saliva is also a likely vehicle for transmission. HHV-8 can also be transmitted via blood products and tissue grafts.

Transmission via allografts and blood products

HHV-8 is transmitted to 25% to 33% of previously uninfected recipients of solid organ grafts taken from a HHV-8-seropositive donor. While KS is a relatively common form of cancer among solid organ transplant recipients, it occurs infrequently. BCBL and MCD have also been reported in allograft recipients. Since HHV-8 can be identified in blood from healthy donors, transmission from blood products is possible but does not appear to occur commonly.

Treatment of HHV-8 infection

At present treatment of HHV-8 infection in immunosuppressed patients, in the absence of disease, is not generally recommended but may be considered in regions of high prevalence. Traditional treatment for KS, MCD, and BCBL includes reduction or elimination of any immunosuppressive treatment, chemotherapy, and/or radiation therapy. The clinical course of AIDS KS has improved greatly in the years since the introduction of cART. Ganciclovir, cidofovir, and foscarnet effectively inhibit HHV-8 and may be used with modifications of immune suppression. Systemic administration of cidofovir, foscarnet, ganciclovir, and α-interferon can induce response or remission in patients with AIDS KS, often in conjunction with antiretroviral therapy and/or chemotherapy. Foscarnet has been successfully used to treat MCD. Foscarnet or ganciclovir may be effective in preventing KS among HIV-infected men, though this approach has been largely displaced by cART. Dosage of the antiviral drugs is based on anti-CMV therapy; specific dosing recommendations for HHV-8 are not available.

189. Influenza

Ramin Sedaghat Herati and Harvey M. Friedman

Influenza infections have caused significant morbidity and mortality throughout recorded human history. Each year, seasonal influenza is estimated to cause around 500 000 excess deaths worldwide. At least 32 pandemics have occurred since 1580 in addition to the seasonal waves of influenza infection. In 1918, a particularly severe pandemic, dubbed the "Spanish flu," led to the rapid spread of influenza and resulted in at least 20 million deaths worldwide. Recently, the possibility of a worldwide pandemic due to pathogenic avian influenza viruses has become of great concern. Significant resources worldwide have been dedicated to the detection and containment of influenza outbreaks and the development of response plans to influenza epidemics at international, national, and local levels.

INFLUENZA VIRAL STRUCTURE

Influenza viruses are enveloped, single-stranded, negative-sense RNA viruses in the family Orthomyxoviridae, which include the genera *Influenzavirus* types A, B, and C. Influenza tends to be spherical and 80 to 120 nm in diameter. Influenza A and B viruses cause the majority of human infections with influenza, whereas influenza C virus causes only sporadic upper respiratory infections. Influenza A viruses can cause infections in birds as well as humans, swine, and other mammals.

Influenza virus has an envelope composed of a lipid bilayer, with a layer of matrix protein on the inner surface and spike-like surface projections of glycoproteins on the outer surface. These glycoproteins include hemagglutinin and neuraminidase. Hemagglutinin is responsible for binding to cells of the respiratory tract expressing sialic acid. Once phagocytosed, hemagglutinin then fuses with the endosome membrane and releases viral ribonucleoproteins into the cytoplasm, which leads to viral replication. In contrast, neuraminidase primarily functions in the last stage of cellular infection by enzymatic cleavage of sialic acid and release of mature virions from the cell surface. Within the envelope of influenza A and B are eight segments of viral RNA encoding polymerase proteins A, B1, and B2, hemagglutinin, neuraminidase, matrix proteins M1 and M2, nucleocapsid protein, and nonstructural proteins NS1 and NS2.

EPIDEMIOLOGY

Antigenic shift and drift

One of the most remarkable features of influenza virus is the frequency of its antigenic change. Therefore, immunity to the influenza viruses is often incomplete. Antigenic shift and antigenic drift are two types of antigenic variation that have been described, principally involving the two external glycoproteins of the virus, hemagglutinin and neuraminidase. Antigenic shift is less common but more dramatic and results from genetic reassortments between human and animal viral strains. Antigenic drift, on the other hand, is produced by single point mutations in the hemagglutinin or neuraminidase genes that result in changes of one or a few amino acids. Antigenic drift is primarily seen in influenza A viruses but can be seen in influenza B viruses as well. Three subtypes of hemagglutinin, H1 (variants H0, H1, Hsw1), H2, and H3, and two subtypes of neuraminidase, N1 and N2, are recognized among human influenza A viruses. Only a few strains of influenza A or B virus tend to dominate during each annual influenza season.

Antigenic shifts can produce immunologically novel strains of influenza A that herald the epidemics and worldwide pandemics. In 2009, infections with a novel H1N1 virus, thought to derive from reassortment of avian, swine, and human influenza viruses, resulted in a pandemic. First recognized as a major threat in April 2009, the virus spread rapidly and may have resulted in

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

over 300 000 deaths within 15 months worldwide. Another influenza virus, avian H5N1, is under close surveillance due to its pandemic potential. It was originally thought to be endemic in many wild bird populations and not pathogenic in humans. However, beginning in 1997, approximately 50 cases of laboratory-confirmed human H5N1 infection have been reported annually. Unfortunately, humans have little pre-existing immunity to H5N1 and an overall case-fatality rate of 60% has been observed. Isolated human-to-human transmission has been observed, but the vast majority of cases have occurred after close contact with infected birds.

The World Health Organization (WHO) is currently leading a global effort to detect and characterize influenza outbreaks before they become pandemics. In 2013, another avian-origin virus, H7N9, was identified in China as a cause of severe respiratory tract infections with numerous case fatalities. In contrast to H5N1, infected birds are asymptomatic and thus environmental surveillance has been challenging. The true incidence and prevalence of H7N9 infections are not yet known.

Transmission

Most influenza infections are acquired through human-to-human transmission of small-particle aerosols. Localized clusters of infection begin rather abruptly, reach a sharp peak in 2 to 3 weeks, and wane in incidence over the subsequent 5 to 6 weeks. Attack rates during such outbreaks can approach 10% to 40%. Although influenza is virtually always active somewhere in the world, seasonal influenza is most common during the winter months. The peak influenza season typically extends from December through April in the Northern Hemisphere. Influenza season is defined by viral isolation, whereas an epidemic is defined by a rise in pneumonia and influenza deaths above the epidemic threshold in the Centers for Disease Control and Prevention (CDC)'s nationwide mortality surveillance system. Although influenza can affect all individuals in a population, severe infections resulting in hospitalization during most influenza seasons generally occur among adults over age 65 and children aged 0 to 4 years.

Immunology

Influenza infection results in activation of the innate and adaptive arms of the immune system. Upon initial infection, innate pattern-recognition receptors including Toll-like receptor 7 (TLR7) "sense" the infection and lead to proinflammatory cytokine production. Dendritic cells acquire and present influenza antigens to T cells, which leads to stimulation of the adaptive immune system. Naïve and memory T cells, including CD4 and CD8 subsets, then mediate a variety of responses including recruitment of additional immune effectors, direct killing of infected cells, and B-cell help. Neutralizing antibodies are produced by B cells and block the ability of free influenza virions from infecting additional cells. After a successful immune response, tissue repair takes place and inflammation returns to baseline, along with the death or egress of most of the responding immune cells. Memory T and B cells are established which respond much more quickly to subsequent infections. For many decades, neutralizing antibody titers have been used as a strain-specific correlate of protection against future infections. A titer of 1:40 or higher indicates that an individual is likely protected. However, this correlate has limitations. Some with low titers are resistant to infection in experimental challenge models, whereas some with very high titers become infected. Work to develop better correlates of protection is ongoing.

CLINICAL MANIFESTATIONS

Uncomplicated influenza

Classic influenza is characterized by the abrupt onset of symptoms including fever, headaches, and myalgias after a short incubation period. Systemic symptoms predominate initially, including chills or rigors, malaise, and anorexia. Severe intraocular muscle pain can often be elicited on lateral gaze. Calf muscle myalgia may be particularly prominent in children. The systemic symptoms usually persist for approximately 7 days and then wane. Respiratory symptoms, such as dry cough and nasal discharge, emerge early during the illness and begin to dominate the clinical presentation as fever resolves. Cough is the most common and troublesome of these later complaints and can take several weeks to resolve.

Complications of influenza

The complications of influenza can be classified as pulmonary and nonpulmonary and result either from progression of the viral process itself or from secondary bacterial infections. Influenza can be associated with a primary influenza viral

Table 189.1 Pulmonary complications of influenza

Feature	Primary viral pneumonia	Secondary bacterial pneumonia
Setting	Cardiovascular disease Pregnancy Young adults (in large outbreaks)	Age >65 years Chronic pulmonary, cardiac, or metabolic disease
History	Rapid progression after typical onset	Biphasic illness, with worsening after clinical improvement
Physical examination	Diffuse crackles	Consolidation
Sputum culture	Normal oral flora	*Streptococcus pneumoniae* *Staphylococcus aureus* *Haemophilus influenzae*
Isolation of influenza virus	Yes	No
Chest radiograph	Diffuse bilateral interstitial disease	Consolidation
Response to antibiotics	No	Yes
Mortality	Variable, high during some pandemics	Variable, generally low

pneumonia and/or a secondary bacterial pneumonia (Table 189.1). Nonpulmonary complications of influenza occur less often and are most prevalent during large outbreaks. These include myositis (more common with influenza B infection), myocarditis, pericarditis, transverse myelitis, encephalitis, and Guillain–Barré syndrome. A toxic shock-like syndrome has occurred in previously healthy children and adults during outbreaks of influenza A or B. This syndrome has been attributed to the effects of the viral infection on the colonization and replication characteristics of toxin-producing staphylococci. Reye's syndrome has also been described in children treated with aspirin during influenza outbreaks. The major causes of death are pneumonia and exacerbation of chronic cardiopulmonary conditions. Of those who die, 80% to 90% are age 65 years or older.

H5N1 infection

Most cases of H5N1 have occurred in healthy young adults, approximately 2 to 4 days after exposure to infected birds. Initial symptoms include high fever and an influenza-like illness. In contrast to infection with human influenza viruses, lower respiratory tract involvement and clinically apparent pneumonia are almost universal. Watery diarrhea may be present before the development of respiratory symptoms. Progression to multiorgan failure, including respiratory failure, renal dysfunction, and cardiac compromise, is common. Atypical presentations, such as encephalopathy, gastroenteritis, and mild respiratory disease, have been reported, but frequencies of such presentations are unknown. Death occurs on average 9 to 10 days after the onset of illness. Asymptomatic infection likely occurs as well, as indicated by antibody screens in populations at risk, but the true incidence is unknown.

DIAGNOSIS

Reverse transcriptase–polymerase chain reaction (RT–PCR) assays are extremely sensitive, specific, and rapid, which has made them the standard for diagnosis. Other rapid assays include immunofluorescence, which requires skilled expertise and has lower sensitivity than RT–PCR. Viral culture is utilized in some areas but takes days to give a result. Serologic tests to measure hemagglutinin neutralizing antibody titers in acute and convalescent sera are not recommended by the CDC for diagnosis due to the delay required to establish the diagnosis. A clinical diagnosis based on fever, headache, myalgias, and cough during influenza season has an accuracy of 60% to 85%. However, influenza cannot be distinguished from other respiratory viruses by symptoms alone, and testing is necessary to know if a patient would benefit from influenza antiviral treatment.

THERAPY

Two classes of antiviral drugs are available for treatment of influenza, including neuraminidase inhibitors (NI) and M2 inhibitors. Zanamivir (Relenza) and oseltamivir (Tamiflu) are two NI approved for treatment of both influenza A and B infection. These agents inhibit neuraminidase activity and prevent viral particle release from infected cells. Zanamivir has poor oral bioavailability and is formulated for oral inhalation using a disk inhaler. Oseltamivir is the ethyl-ester prodrug of the active compound and is well absorbed orally. When given within 48 hours after the onset of symptoms, NI decrease the duration of symptoms by about 1 day. Meta-analyses

indicate a reduction in the incidence of influenza-related complications including pneumonia and bronchitis when administered early during the course of an infection. There are insufficient data as to whether NI are effective treatment of these complications once they occur, but they may have some modest benefit. These agents are generally well tolerated, although zanamivir can cause bronchospasm and respiratory compromise in patients with chronic respiratory diseases. Infection with NI-resistant virus occurs sporadically but likely has only a limited impact on public health. Despite resistance developing during treatment with oseltamivir in up to 25% of individuals, transmission of resistant strains is uncommon. New agents under active development include peramivir (intravenous) and laninamivir (inhaled), which are long-acting NI. They are effective against viruses resistant to oseltamivir and can be administered as a single dose.

The M2 inhibitors, amantadine and rimantadine, are an older class of drugs approved for the treatment of influenza. The M2 inhibitors prevent viral replication by blocking the M2 protein ion channel, thus preventing fusion of the virus and host cell membranes. Both drugs have been shown to reduce the duration of symptoms of clinical influenza and decrease the severity of fever and other symptoms in randomized trials. However, they have been associated with several adverse effects. For example, amantadine causes reversible central nervous system (CNS) toxicities, including insomnia, dizziness, nervousness, and difficulty concentrating, especially in the elderly. Viral resistance to M2 inhibitors has increased over time among influenza A isolates, and their use has not been recommended during recent influenza seasons. These agents are not active against influenza B.

PREVENTION

Vaccine

Vaccination is the mainstay of influenza prevention. Because influenza viruses undergo frequent antigenic alterations, a new vaccine containing antigens predicted to predominate in the upcoming winter epidemic is prepared each year. The CDC, in conjunction with the WHO, tracks influenza activity throughout the world to predict the components of the annual influenza vaccine. The majority of administered vaccines target two strains of influenza A and one strain of influenza B. The inactivated influenza intramuscular vaccine (IIV) is the most commonly administered version and is more immunogenic in adults, whereas the live attenuated intranasal vaccine (LAIV) is less frequently used and is more immunogenic in children. The latter has the potential to produce mild signs and symptoms of influenza infection because it contains live virus.

The protective efficacy of influenza vaccination depends on the similarity between the viruses used in the vaccine and those in circulation, as well as an individual's age and immune status. In healthy adults younger than 65 years, a well-matched vaccine is 70% effective at preventing influenza illness. During poorly matched seasons, efficacy is 30% to 50% among healthy persons. In older adults, efficacy is even lower and the number of vaccine nonresponders increases. However, vaccination is nonetheless effective at decreasing hospitalization, secondary complications, and death due to influenza. A high-dose IIV vaccine has been approved for use in older adults but efficacy data are lacking. A recombinant IIV has been developed which reduces vaccine production time and eliminates the need for eggs. Among human immunodeficiency virus (HIV)-infected individuals, efficacy is lowest among those with low CD4 counts ($\leq 200/mm^3$) and uncontrolled HIV viremia. Individuals receiving antiretroviral therapy probably derive protection from vaccination but not as effectively as HIV-uninfected adults. Regardless, all HIV-infected patients should be vaccinated against influenza to prevent morbidity and mortality. Similarly, solid organ transplant recipients also derive less benefit from vaccination but should be vaccinated annually.

Contraindications to influenza vaccination are few. Individuals who have a severe allergic reaction to influenza vaccination should not be vaccinated, although such cases are exceedingly rare. Individuals with moderate or severe acute febrile illnesses usually should not be vaccinated until their symptoms have abated. However, minor illnesses with or without fever are not a contraindication. The LAIV is approved only for healthy, nonpregnant individuals between ages 2 and 49 years. Although a history of Guillain–Barré syndrome after vaccination and egg allergies are not formal contraindications to vaccination, extra precautions should be taken when vaccinating these individuals. The optimal time for organized vaccination campaigns for persons in high-risk groups is typically October through December. Recommendations for the use of influenza vaccine are listed in Table 189.2.

Table 189.2 Available seasonal influenza vaccines.

Vaccine	Recommended recipients	Contraindications
Inactivated influenza vaccine (IIV)	All individuals over 6 months of age	History of severe allergic reaction to this vaccine[a]
Inactivated influenza vaccine (IIV), high dose	All adults over age 65	History of severe allergic reaction to this vaccine[a]
Live attenuated influenza vaccine (LAIV)	Healthy, nonpregnant, ages 2–49 years	History of severe allergic reaction to this vaccine[a] Immunosuppressed patients, healthcare personnel in close contact with immunosuppressed populations, children with history of asthma or severe wheezing
Recombinant influenza vaccine, trivalent	Adults ages 18–49	History of severe allergic reaction to this vaccine[a]

[a] *Note*: Individuals with active moderate or severe febrile illness usually should not be vaccinated until symptoms have abated. Individuals with a history of egg allergy may receive these vaccines if administered with additional observation and safety measures. History of Guillain–Barré syndrome within 6 months of receipt of an influenza vaccine is considered to be a precaution for future vaccinations.

Adapted from Interim Recommendations: Prevention and Control of Influenza with Vaccines: Recommendations of the Advisory Committee on Immunization Practices (ACIP), 2013.

Chemoprophylaxis

Chemoprophylaxis is an important adjunct to vaccination. Vaccination-induced neutralizing antibodies to influenza peak at 2 to 3 weeks after vaccination. Thus chemoprophylaxis may be considered in high-risk individuals until immunity develops. Some high-risk individuals, such as organ transplant recipients, have poor responses to vaccination and should be considered for additional protection with chemoprophylaxis. Chemoprophylaxis may also be effective at controlling outbreaks in chronic care settings.

The NI, oseltamivir and zanamivir, are approved for prophylaxis of influenza A and B. When given to healthy adult volunteers, both zanamivir, at a dosage of 10 mg/day over a 4-week period, and oseltamivir, at 75 mg/day over a 6-week period, reduced laboratory-confirmed cases by 82% and 84%, respectively. Both drugs are effective at decreasing secondary spread of influenza. Lower rates of influenza among household contacts of suspected cases of influenza were documented in patients who took zanamivir for 10 days or oseltamivir for 7 days compared with placebo. Amantadine and rimantadine are approved for use as prophylactic agents against influenza A virus, but high rates of drug resistance in circulating influenza strains from recent years have rendered these agents unreliable.

PANDEMIC PREPAREDNESS

The emergence of the avian influenza virus, H5N1, has raised awareness of the possibility of a severe, worldwide influenza pandemic. By some estimates, 30% or more of individuals could become ill during a pandemic. Healthcare systems will likely become overwhelmed, and supplies such as vaccines, antivirals, antibiotics, ventilators, and personal protective equipment will be in short supply. Very likely, there will not be adequate hospital beds to meet healthcare needs. Public health measures, including school closings, travel bans, and individual quarantine, may cause significant social disruption. Absenteeism could exceed 40% and have profound effects on commerce, the economy, and the supply of goods and services.

Proper planning could lessen the effects of a pandemic on society. Preparedness on federal, state, and local levels is crucial, but business and healthcare sectors as well as individuals must also prepare. Hospitals, clinics, and long-term care facilities are encouraged to develop pandemic preparedness plans that include the development of surveillance systems for identifying potential outbreaks, plans for communication (i.e., with public officials, employees, and patients), strategies for dealing with surges in patient volume (including triage, admissions, cohorting, and facility access), and protocols for dealing with sick and exposed employees and the reassignment of worker duties. Other important issues include developing guidelines for the distribution of antivirals, vaccine, and medical supplies that may be limited. Healthcare workers should also encourage patients to develop their own pandemic preparedness plans with their families.

The CDC provides checklists, guidelines, and suggestions for pandemic planning in health care,

family, school, business, and community, state, and local government settings. Given the likely limited availability of vaccine and antiviral medication during the initial waves of a pandemic, the CDC is also promoting nonpharmacologic interventions to limit transmission of the virus. This strategy has been termed *targeted layered containment* and includes isolation of ill persons and voluntary quarantine of household contacts, social distancing measures (i.e., school closure, increased use of telecommuting in the workplace), cancellation of public events and public gatherings (including closure of houses of worship), and individual infection control measures (such as hand hygiene and cough etiquette).

190. Papillomavirus in oro-genital infection

Lawrence J. Eron

Human papillomaviruses (HPV) cause 10 000 cases of squamous cell carcinoma (SCC) of the cervix each year in the United States, as well as 3700 deaths annually. It is the third most common cancer in women worldwide. The virus also causes genital warts, the most common sexually transmitted disease in the United States with an annual incidence of 5.5 million cases and a prevalence of 20 million infections (Figure 190.1). Peak prevalence of infection occurs during the first 10 years following sexual debut, between 15 and 25 years of age. The National Health and Nutrition Examination Survey (NHANES) study found a 25% prevalence of HPV DNA from vaginal swabs of 20- to 24-year-olds. Because HPV produces persistent infection that in most cases is subclinical (and therefore undetected) and because the virus is easily transmitted via intercourse, 80% of sexually active people are infected during their lifetime.

Rates of transmission differ according to body site: Transmission from penis to cervix is 58.8 cases per 100 patient years; from cervix to penis is 208.8 cases per 100 patient years. Nonpenetrative intercourse transmits HPV from the anus to the scrotum and from the hand to the penis.

GENITAL HPV INFECTION

Of the more than 100 different DNA types of HPV, distinguished on the basis of relatedness of their genomes, 40 infect the genital area. These 40 genital types fall into two groups, distinguished by the type of disease that they produce. The first group, which includes the two most common HPV types, 6 and 11, causes exophytic condylomata, referred to as genital warts (Figure 190.2), as well as low-grade dysplasia of the vulva, vagina, and cervix.

The second group, typified by types 16 and 18, causes SCC as well as high-grade dysplasia of the cervix, vagina, vulva, and penis, which appears as white areas of skin after the application of acetic acid (Figure 190.3). Low-grade dysplasia is referred to as squamous intraepithelial lesions (SIL) grade I, moderate dysplasia as SIL grade II,

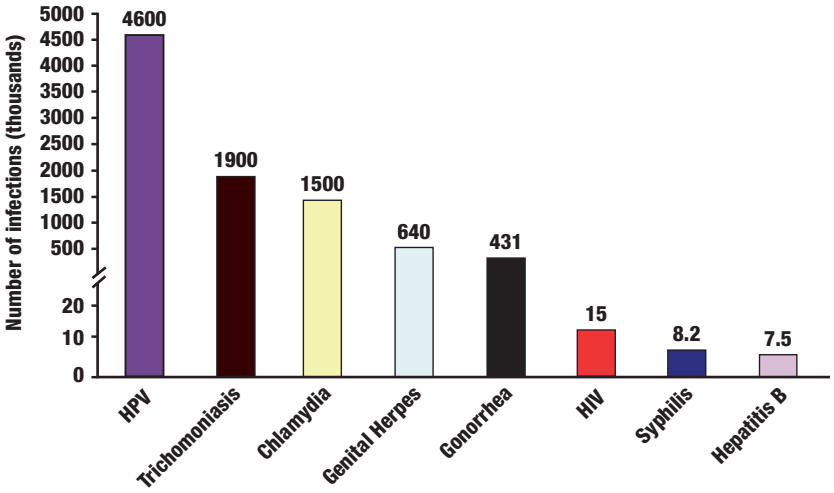

Figure 190.1 Human papillomaviruses (HPV) are the cause of the most common sexually transmitted disease, genital warts, with an annual incidence of 6.2 million and a prevalence of 20 million infections. HIV = human immunodeficiency virus.

Figure 190.2 Exophytic condylomata, also referred to as genital warts.

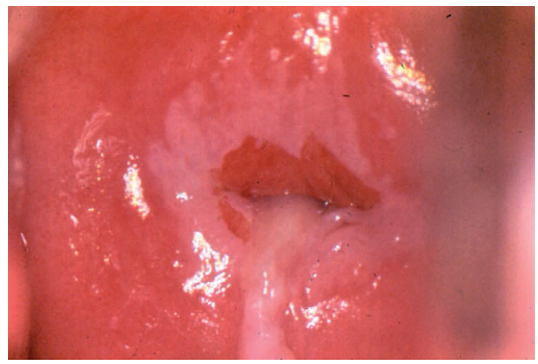

Figure 190.3 High-grade dysplasia of the cervix, vagina, and vulva, appears as white areas after the application of acetic acid.

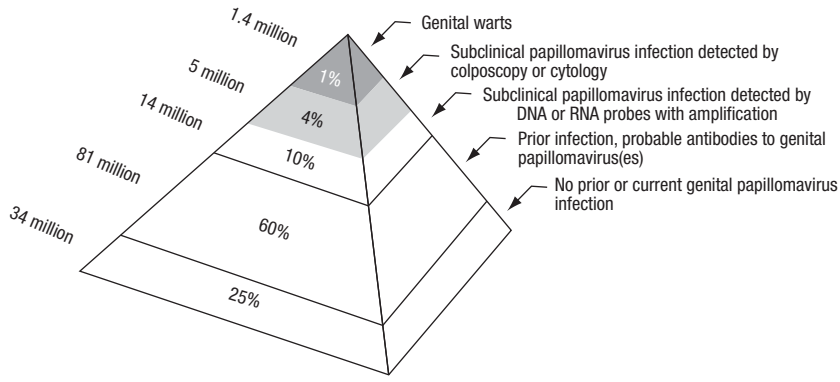

Figure 190.4 Human papillomaviruses may produce asymptomatic infection, subclinical disease, or clinically apparent disease.

and severe dysplasia as SIL grade III. When the cervix is affected, it is termed cervical intraepithelial neoplasia (CIN) with similar grading as SILs. Both groups of HPV viruses may produce asymptomatic infection, subclinical disease, or clinically apparent disease (Figure 190.4).

HPV may also infect the perianal region and the distal rectum above the dentate line. In people infected with human immunodeficiency virus (HIV), HPV may produce small, innocent-appearing ulcers that on biopsy are proven to be SCC. HIV infection, as well as other immunodeficiency states, increases the likelihood that dysplastic lesions of the cervix may evolve into invasive carcinomas. Recurrent or refractory genital warts may be surrogate markers for concomitant infection by HIV, and it is important to test for HIV in patients with HPV infection.

Despite the enormous prevalence, HPV infections in the majority of woman usually resolve in 6 to 12 months. Up to 30% of infections by low-grade HPV types 6 and 11 may be transient. and will not evolve into a malignant state. Although moderate or severe dysplasia may also remit without treatment, women with these lesions should be evaluated by colposcopy to detect the development of carcinoma *in situ*. Women with persistent infection by the oncogenic HPV types are at risk for developing precancerous and cancerous lesions (Figure 190.5).

HPV CAUSES MOST CANCERS OF THE OROPHARYNX

SCC of the oropharynx are associated with either tobacco/alcohol/betel nut use or HPV infection. HPV type 16 and, less commonly, types 18, 31, and 33 are found in 80% of these tumors. In SCC of the tobacco/alcohol/betel nut type, the host p53 and retinoblastoma oncogenes (pRb) are altered by the virus, while p16, a tumor suppressor, is decreased. In contrast, HPV-associated SCC of the oropharynx contains no mutations of the p53 oncogene and expression of pRb is down-regulated, while p16 is upregulated. HPV+

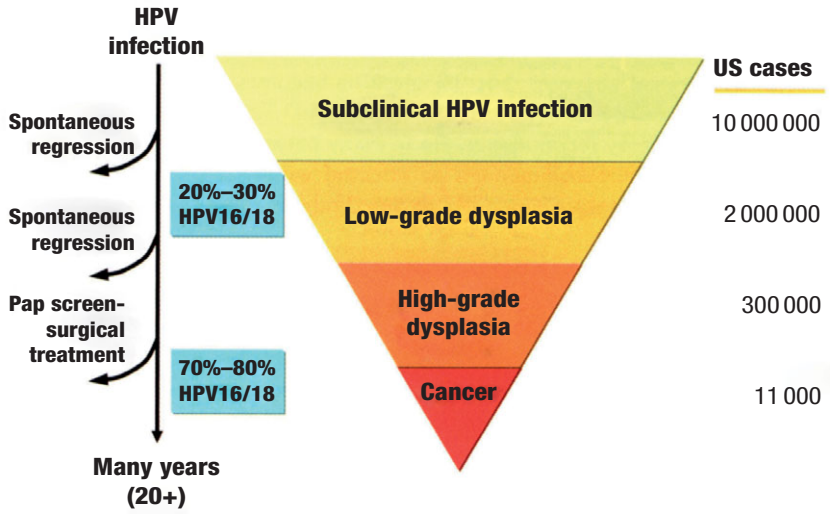

Figure 190.5 Infection by low-grade human papillomavirus (HPV) types may be transient.

tumors arise in the base of the tongue and tonsillar region, and show a much better response to chemotherapy than the other type.

HPV may be transmitted through open-mouthed kissing as well as oral sex. Among men with no oral sexual contacts, the risk of oral HPV transmission varies with the number of kissing partners. While the overwhelming majority of oral HPV infection clears with no intervention, the increasing prevalence of HPV-positive SCC of the oropharynx raises the question as to the benefit of vaccinating boys as well as girls, and at even earlier ages, to prevent oral, as well as sexual, transmission of HPV.

DIAGNOSIS OF HPV INFECTION

The methods used to diagnose HPV infection include cytologic exam via the Pap smear, colposcopy and biopsy, and tests for HPV DNA. Colposcopy of the cervix is useful when there is moderate to severe dysplasia. While HPV DNA testing improves the sensitivity of detecting infection, it lacks specificity, leading to unnecessary colposcopy. HPV DNA testing for primary screening is only recommended for women >30 years old, as younger women very often have self-limited infection.

PRINCIPLES OF THERAPY

The main problem with treatments that extirpate clinically evident disease is that they do not eliminate the underlying HPV infection. The epithelium of healthy-appearing skin around a genital wart may be subclinically infected with HPV up to 1.0 cm from the actual lesion. Because the virus can be shed asymptomatically from apparently normal tissue adjacent to the treated areas, and removal of a wart or dysplastic tissue has not been shown to decrease transmissibility of HPV infection, this shedding may be the mechanism of recurrence following treatment. Because many external genital warts resolve spontaneously and there is little likelihood that the viral reservoir can be eliminated by treatment, the primary goal of treatment of external genital warts is to ameliorate symptoms. Although infections are often asymptomatic and many cases will resolve spontaneously, patients with genital warts often experience depression and a sense of social isolation.

Topical treatments may be either cytotoxic (e.g., podophyllotoxin) or immune-mediated (e.g., imiquimod), both of which may be self-applied. These treatments are recommended for exophytic condylomata. Both types of treatments have similar efficacy (~60%) and recurrence rates (~30%).

For moderate to severe dysplasia of the cervix, vagina, vulva, and the penis cytodestructive procedures such as surgical excision and cryotherapy using liquid nitrogen may be effective.

Both surgical excision and cryotherapy are equally effective (~80%) and have similar relapse rates. Loop electrical excisional procedure (LEEP) and laser ablation of dysplastic tissue of the cervix may be more effective (~90%) than surgical excision or cryotherapy. However, recurrences still occur (~29%). Modulating the immune

response to decrease persistent infection and recurrence rates following treatment is the "holy grail" of HPV treatment.

IMMUNITY TO HPV INFECTION

Although the prevalence of HPV infection is high in young women, only a minority (≤5%) of infected women develop persistent infection and progress to SIL. In most cases, infection may be transient if the individual develops a sufficient immune response to the virus. When infection of the cervix by HPV 16 or 18 becomes persistent, SILs and CIN may evolve to SCC usually several decades later.

Seroconversion following HPV infection occurs in only 60% of infected females and far less frequently in males. HPV may evade the immune system since its replication does not induce cytolysis, necrosis, or viremia. Viral proteins are released only in terminally differentiated epithelial cells, which are programmed for apoptosis and thus evade immune surveillance. Furthermore, HPV inhibits the synthesis of interferon and other cytokines.

Viral, environmental, and host factors play a role in the evolution of infection to the development of SIL/CIN and thence to SCC. Polymorphisms among HPV type 16 variants are associated with longer persistence, more aggressive infection, and higher frequency of SCC. Environmental factors that are associated with progression of SIL to SCC include smoking, long-term oral contraceptive use, high parity, and coinfection with other sexually transmitted diseases (STDs). Host factors associated with increased susceptibility to SCC include genetic polymorphisms in the major histocompatibility complex (MHC) genes which decrease class I MHC cell surface expression and in TAP proteins associated with antigen processing, thereby interfering with host immune response.

THE HPV GENOME AND CARCINOGENESIS

HPV contains a circular, double-stranded DNA genome, consisting of eight structural genes in two distinct regions (Figure 190.6). The early region is composed of six genes (E1–E2 and E4–E7) that control viral replication, transcription, and cell transformation. The late region is composed of two genes (L1 and L2) that encode the viral coat proteins. The "long control region" regulates the expression of these eight genes. In productive infection, as is the case for types 6 and

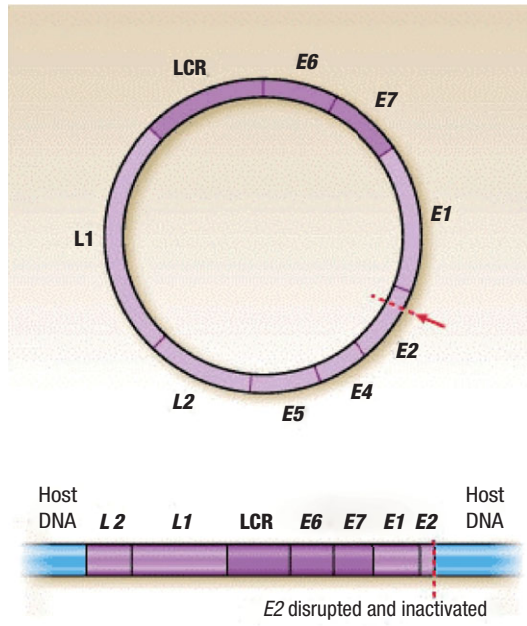

Figure 190.6 Human papillomavirus contains a circular, double-stranded DNA genome, consisting of eight structural genes in two distinct regions.

11, both early and late regions of the virus are transcribed into messenger RNA (mRNA), which codes for proteins essential for viral DNA replication and for coat proteins. Many copies of HPV DNA are produced in each infected cell as circular, extrachromosomal plasmids. The net result is mature infectious virions.

In contrast to productive infection, when type 16 or 18 infects a cell, late genes are not transcribed, viral coat proteins are not synthesized, and no mature virions are produced. Instead the circular HPV genome inserts itself into the host chromosome, disrupting its E2 gene, resulting in the loss of E1 and E2 gene functions (Figure 190.6). Normally E1 and E2 downregulate E6 and E7 expression, but with the loss of E1 and E2 control, E6 and E7 functions are upregulated. The E6 and E7 gene products then alter host oncogenes (p53 and pRb, respectively) that normally control cell growth and differentiation by arresting host cell division in the G1 phase. This normally allows the cell time to repair damaged DNA before progressing to the S (DNA replication) phase. The loss of this repair mechanism results in cell transformation, which renders the host genome susceptible to other carcinogens, such as smoking. The time between initial HPV infection and the development of SCC is between 10 and >20 years.

HPV PREVENTION

Because the viral genome is highly conserved and because HPV uses cellular enzymes to replicate (and thus cannot easily develop resistance in contrast to HIV for example), effective vaccines (Gardasil and Cervarix) have been developed that produce neutralizing antibodies that protect against viral infection. In addition the vaccines also produce cytotoxic CD8 lymphocytes that eliminate nascent HPV-infected cells. The vaccines are ~95% effective in the prevention of infection by HPV types 16 and 18 (which represent 70% of oncogenic HPV types). The Gardasil vaccine is also highly effective (90%) against HPV types 6 and 11 that produce condylomata.

Vaccine administration is recommended for females, ages 11 to 26, to induce immunity prior to the female sexual debut, which in 77% occurs by age 19. Following the sexual debut, the incidence of HPV infection rises to 40% within 2 years and to >50% within 4 years, at which point the vaccine is likely to be ineffective. Widespread vaccination of males would induce herd immunity in females and would prevent oropharyngeal cancers caused by HPV 16 and 18 in 93% and 100% of males, respectively. The vaccines offer durable protection against HPV types contained in the vaccines for at least 5 years, but are woefully underutilized in the United States as compared to Australia where an 80% vaccination rate of young girls has very nearly eliminated condylomata from not only females but also males <21 years of age, indicating herd immunity. Furthermore, high-grade lesions have also decreased in girls <18 years old.

In addition to vaccines, the most cost-effective strategy for reducing HPV infection is the consistent use of condoms. In a well-designed and executed study, condoms reduced the incidence of genital HPV infection from 89.3 per 100 patient-years to 37.8. In those women whose partners used condoms 100% of the time, there were no cervical SILs observed in 32.1 patient-years, whereas 14 SILs were detected in 96.8 patient-years among women whose partners used condoms less than 100% of the time.

Because the HPV genome contains two oncogenes, E6 and E7, that are involved in the production of SCC, vaccines against the products of these genes could be used theoretically to prevent or treat cervical cancer. While in animals such a vaccine can protect against challenge with tumors expressing E6 and E7 antigens, no such results have been reported in humans.

191. Acute and chronic parvovirus infection

Neal S. Young

Parvoviruses are small viruses with unenveloped icosahedral capsids that contain a single-stranded DNA genome. These physical properties contribute to viral resistance to heat, solvents, and extreme chemical conditions. Because of their limited genome, parvoviral propagation depends on infection of mitotically active cells. B19 parvovirus is the only member of the Parvoviridae family known to cause diseases in humans (although other parvoviruses recently have been isolated from human blood and tissue, their pathogenicity remains uncertain). In the taxonomy of the parvovirus family, B19 and closely related simian parvoviruses constitute the *Erythrovirus* genus, separated from autonomous animal parvoviruses, dependoviruses (which require coinfection with a second virus for efficient propagation in cell culture), and insect parvoviruses called densoviruses.

B19 parvovirus has a peculiar and extreme tropism for human erythroid progenitor cells, which are responsible for the generation of circulating erythrocytes. In tissue culture, B19 has been propagated in hematopoietic cells: bone marrow, fetal liver, peripheral blood, and (rather inefficiently) in a few leukemic cell lines. B19 viral DNA replication in patients has been detected in blood and marrow. Specificity for erythroid cells follows from the cellular receptor for the virus, globoside or P antigen, a tetrahexose ceramide present on erythroid cells, megakaryocytes, endothelial cells, and some placental cell types, as well as fetal liver and heart. Parvovirus infection is terminated by host production of neutralizing antibodies. Failure to produce neutralizing antibodies can result in persistent infection. Cellular immune responses to parvoviruses have been measured and some CD4 and CD8 T-cell epitopes defined.

B19 DISEASES

Serologic studies have shown that more than half of the adult population has antibodies to B19 parvovirus; although most infection occurs during childhood, the seropositivity rate continues to rise with age. Probably the majority of infections are asymptomatic. Reliable diagnostic assays are now widely available. The presence of immunoglobulin G (IgG) to virus only signifies past infection. Immunoglobulin M (IgM) or virus DNA detected by direct hybridization testing indicates recent infection. The interpretation of a positive DNA study obtained by gene amplification (polymerase chain reaction) is more problematic, as individuals may not clear small amounts of virus for many months after an acute infection, and laboratory contamination can produce false positives.

Fifth disease

This common childhood exanthem is caused by acute parvovirus infection. The slapped-cheek rash and the evanescent maculopapular eruption over the trunk and proximal extremities are typical (Figure 191.1). Children may be febrile but usually have few symptoms. Meningitis and encephalitis have been reported as very rare complications. The blood of children with fifth disease contains IgM antibody to B19 but little if any virus; because the syndrome is due to immune-complex formation between virus and antibodies, affected individuals are not considered infectious. Reassurance and antipyretics as needed are sufficient for this self-limited illness.

In adults, acute parvovirus infection may be more serious. Adults have more rheumatic complaints than do children, and there may be frank joint inflammation and a pattern of distribution and chronicity mimicking rheumatoid arthritis; occasionally rheumatoid factor will be present. In most cases, symptoms resolve within a few days or weeks, but in some individuals the arthropathy and systemic symptoms become chronic and debilitating, although there is no joint destruction. The pathophysiology of the rheumatic manifestations after B19 infections is not well

Figure 191.1 Fifth disease; note characteristic maculopapular rash with "slapped cheek" appearance.

understood, but symptoms usually can be addressed with conventional anti-inflammatory drug therapy. Parvovirus is not a cause of rheumatoid arthritis.

Transient aplastic crisis and other hematologic syndromes

Transient aplastic crisis is caused by parvovirus infection in patients who have hemolytic anemia, compensated hemolysis (as in many cases of hereditary spherocytosis), or an increased demand for red cell production (iron deficiency, acute hemorrhage). B19 briefly interrupts erythropoiesis in most persons infected but without consequence because of the long survival of circulating red blood cells. Transient aplastic crisis is manifested by anemia, reticulocytopenia, and red cell aplasia in the marrow. There may be moderate thrombocytopenia and neutropenia in addition to the severe anemia, especially in patients with functioning spleens. The syndrome may be accompanied by marrow necrosis and has been fatal, especially in young children. As the anemia is self-limited, transfusion is adequate therapy. Specific antibody production terminates the episode and likely prevents recurrence.

Figure 191.2 Hydrops fetalis (see text).

Hydrops fetalis and congenital infection

Parvovirus infection of the pregnant woman may be transmitted to the fetus. Midtrimester events have been best characterized; first trimester infection may result in abortion, and third trimester infection has not been associated with adverse outcomes. Infection of the fetus is predominantly in the liver, the site of red cell production; the heart may also be affected (fetal myocardial cells express P antigen). Untreated, the fetus develops severe anemia and heart failure leading to the massive edema of hydrops and death at birth or shortly afterward (Figure 191.2). In utero blood transfusions have apparently been successful in a

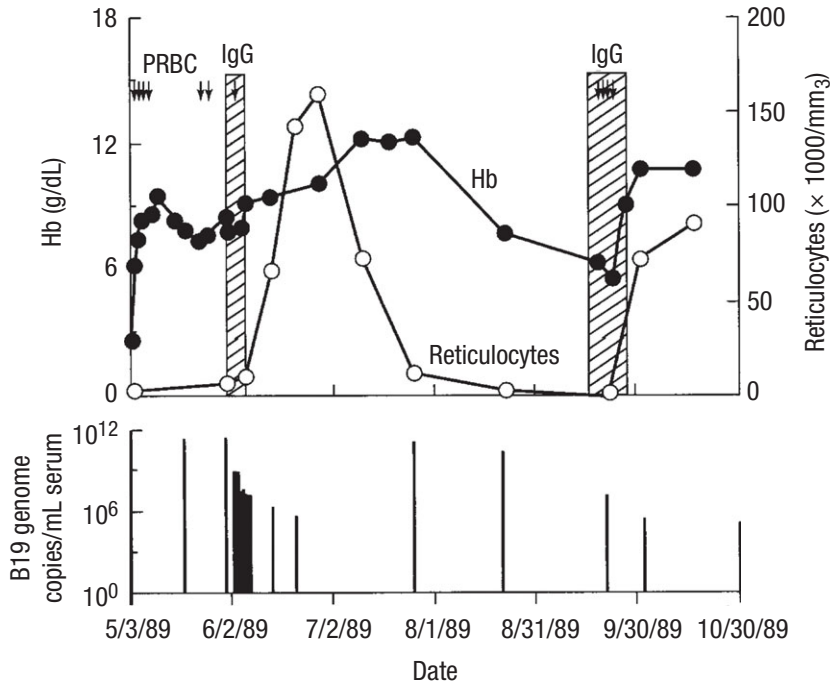

Figure 191.3 Immunoglobulin G (IgG) treatment of B19 persistence in acquired immunodeficiency syndrome (AIDS), illustrating recurrence predicted by molecular studies and the effectiveness of repeated treatment. PRBC = packed red blood cells.

few instances; however, untreated fetal infection need not result in mortality or morbidity. As ultrasound diagnosis may not be definitive, a conservative recommendation is to document progressive hydrops on serial testing before intervention.

Congenital parvovirus infection after transfusion treatment of hydrops can produce chronic anemia from birth. Only a few infants have been described: In all, virus was localized to the marrow and did not circulate, and gene amplification was required to detect the low levels of B19 DNA. The pathology of the marrow was erythroid hypoplasia (Diamond–Blackfan anemia) or erythroid dysplasia resembling congenital dyserythropoietic states. Immunoglobulin therapy has not been effective.

Persistent infection

In the absence of an appropriate immune response, B19 infection can become chronic. Persistent infection has been observed in congenital immunodeficiency (Nezelof syndrome), acquired immunodeficiency syndrome (AIDS) secondary to human immunodeficiency virus (HIV) 1 infection, and during therapy with cytotoxic or immunosuppressive drugs. The deficit in the immune response may be subtle; B19 infection may be the only evidence of constitutional immunodeficiency and the first sign of AIDS. Clinically, the patients have typical pure red cell aplasia with severe anemia, absent reticulocytes in the blood, and a paucity of red cell precursors in the marrow. Scattered giant pronormoblasts, a morphologic feature of B19 infection, may signal the diagnosis, which is established by DNA hybridization studies of serum.

Persistent infection results from inability to mount an effective humoral immune response, measured either as neutralizing antibodies in functional tissue culture experiments or by immunoblot binding of viral capsid proteins. Most AIDS patients lack any antibodies to B19; some congenital cases may have circulating IgM to B19 suggestive of a class-switch abnormality. Fortunately, commercial immunoglobulin preparations are a good source of effective antibodies to parvovirus. Administration of IgG 0.4 g/kg/day intravenously for 5 to 10 days terminates infection. The reticulocyte count dramatically increases after the first week, the marrow shows healthy normoblastic erythroid proliferation, and the hemoglobin rises to a level appropriate for the patient. Treatment can be curative, and the virus may no longer be detectable in some patients who have congenital immunodeficiency or whose immunosuppressive therapy is discontinued. AIDS patients have intense chronic parvoviremia, and IgG treatment appears to reduce but not eliminate the virus (Figure 191.3). Although

relapse after some months is common, recurrent anemia responds to a second course of IgG. Monthly maintenance injections of IgG have been used in a few patients.

OTHER POSSIBLE ASSOCIATIONS

Accumulated case reports are suggestive of a link between B19 and neonatal and childhood myocarditis (P antigen is present on fetal heart cells), a variety of pediatric neurologic syndromes, and some cases of acute, self-limited hepatitis. The association of B19 parvovirus with other clinical syndromes is less secure. Apparent links to childhood neutropenia, idiopathic thrombocytopenic purpura, vasculitis, and juvenile rheumatoid arthritis have not been reproducible. A major technical problem has been the use of gene amplification methods, which not only are susceptible to false-positive results but also are positive in a high proportion of normal individuals: Viral DNA has been found in almost half of knee joints biopsied for trauma and in 20% of normal bone marrows using this sensitive method. Polymerase chain reaction-derived data that are reported without other clinical or serologic evidence of recent infection should be especially suspect. In addition, paroxysmal cold hemoglobinuria, a severe childhood hemolytic anemia that usually follows a viral illness, is a good candidate as a B19 parvovirus syndrome because of the presence of the pathogenic Donath–Landsteiner antibody, directed against erythrocyte P antigen, the virus's cellular receptor.

VACCINE DEVELOPMENT

Effective vaccines to prevent parvovirus infection in animals have been produced by tissue culture modification of virus. For B19, which resists conventional cell culture, recombinant empty capsids have been produced in a baculovirus system by expression of a portion of the parvovirus genome; they contain no viral DNA. Capsids enriched for the highly immunogenic VP1 protein elicit strong neutralizing antibody responses in test animals and, with the appropriate adjuvant, in normal volunteers. The limitation to development of a vaccine is commercial – the perceived market – rather than scientific.

192. Rabies

Gloria von Geldern, Anita Mahadevan, Susarla K. Shankar, and Avindra Nath

HISTORY

The first clear reference to rabies was from writings by Aristotle in circa 380 BC in which he described the symptoms and transmission of rabies in dogs. Despite centuries of observations on the transmission, symptoms, and a myriad of unsuccessful remedies, the disease remained invariably fatal until approximately 1885, when Louis Pasteur developed the first rabies vaccine in Paris. Unable to identify the organism – indeed unaware of even the difference between bacteria and viruses – he cultured it in the spinal cords of rabbits and, ultimately, injected it into Joseph Meister, a young boy attacked by a rabid dog on his way home from school. Given the severity of his wounds on his face, hands, and legs he undoubtedly would have died; however, he received a series of 13 injections, survived, and subsequently spent his life working as a guard at the Pasteur Institute.

EPIDEMIOLOGY

In 2010, the Centers for Disease Control and Prevention (CDC) reported that there were 6153 cases of rabies in animals and 2 human cases in the United States. Hawaii has been the only state free of rabies infection in humans and animals. Ninety-two percent of cases were in wild animals. In Europe, the World Health Organization (WHO) reported 6065 cases of animal rabies and 9 human cases in 2012. Most of these occurred in Eastern Europe. In Latin America, there were 111 cases of human rabies reported between 2010 and 2012. The highest prevalence of rabies worldwide is still in developing countries, with India being in the lead followed by China, Nepal, and Myanmar. A rising incidence has also been seen in some African countries such as Malawi. In the United States the largest reservoirs remain in raccoons followed by skunks, bats, foxes, and coyotes. Raccoon and fox reservoirs are mainly from the eastern states; bat and skunk cases were also found in parts of the south, Pacific Northwest, and California. Domestic animals only accounted for about 6.8% of rabies. Interestingly, cats are found to be infected with rabies almost double the infections of dogs. The cases of rabid cats continue to rise, whereas the cases in other animals are declining yearly. This paradox may be due to administration of vaccines in certain animals, especially dogs. In Europe, the rabies reservoir is mainly the fox, whereas the bat is the main reservoir in Australia, Mexico, and parts of South America. Worldwide, death from rabies is usually from a rabid dog.

PATHOGENESIS AND PATHOLOGY

Rabies is caused by a number of different species of neurotropic viruses in the Rhabdoviridae family, genus *Lyssavirus*. The virus replicates at the wound site for a period of days and then, via retrograde axoplasmic flow, moves up the peripheral nerves to the anterior horn cells in the spinal cord and then trans-synaptically to the brain. Both sensory and motor nerves can propagate the infection. Once the central nervous system (CNS) is seeded with the virus, it then centrifugally spreads back to the periphery. This process involves infection of non-neural tissues, especially the salivary glands, whereby the viral transmission occurs.

Histologic examination of the brain shows perivascular inflammation of the gray matter, neuronal degeneration, and the characteristic cytoplasmic inclusions called the Negri bodies (Figure 192.1A). Renal tubular necrosis has also been demonstrated at autopsy. In 2005 and in 2012, cases of rabies were also reported from organ transplant recipients. Neuropathologic features in the latter showed Duret hemorrhages, widespread neuronal loss, perivascular lymphocytic infiltration, and extensive spinal cord pathology. The case in 2012 was unusual in that rabies occurred 18 months after the kidney transplant

and three others who received organs from the same donor remained asymptomatic likely due to a low dose of the inoculum.

CLINICAL SYMPTOMS

The clinical course in humans is acute, usually progressing from initial symptoms to death within 2 to 3 weeks, even with intensive supportive care. The incubation period of rabies can vary from a few days to several years with an average of 1 to 2 months. The length of the incubation period varies with the infecting strain and is thought to be inversely related to the size of the inoculum and the proximity of the bite to the CNS. Approximately half of the patients develop pain or paresthesias at the wound site. A diagnosis of rabies should not always depend on a history of an animal bite. Exposure may not be obvious in bat-acquired rabies, which often gets misdiagnosed. The prodrome includes low-grade fevers, loss of appetite, and anxiety. Most patients have "furious rabies" characterized by marked hyperactivity, disorientation, hallucination, or bizarre behavior, which lead to an initial psychiatric evaluation. This hyperactivity later becomes intermittent and may be spontaneous or precipitated by tactile, auditory, or visual stimuli. Hydrophobia (spasm of the pharynx and larynx provoked by drinking or the sight of water) and aerophobia (similar effect produced by blowing air on the face of the patient) are considered hallmarks of the disease. The inability to swallow from paralysis of bulbar muscles may also result in hypersalivation. Seizures, which are more common in children, may also occur during this stage, as can dysfunction of the autonomic nervous system. Rarely, there may be respiratory

distress with medullary involvement. A few patients die during this stage, but most go on to develop progressive paralysis and eventually coma. Abnormal cranial nerve, motor, and sensory examinations; tremor; myoclonus; and local sensory symptoms at the exposure site are more common in bat-acquired rabies. In some patients, the paralytic state dominates the entire clinical picture; hence, it is termed *paralytic rabies*. Paralysis or paresis involves the proximal muscles and can be accompanied by constipation, urinary retention, and respiratory failure. Alternatively, inflammation with demyelination and axonal dysfunction of the peripheral nerve causes an ascending lower motor neuron weakness without anterior horn cell involvement. Physical exam shows a motor weakness involving the respiratory muscles and loss of deep tendon reflexes with maintained consciousness which may mimic an acute axonal Guillain-Barré syndrome. This lack of involvement of spinal cord motor neurons and brainstem is called an "escape phenomenon." In some patients, however, the clinical manifestations can be nonspecific; hence, in all patients with unknown cause of progressive encephalitis, the possibility of rabies should be considered. In patients receiving intensive supportive care, the average duration of illness between onset of paralysis and death is 7 days. Once neurologic symptoms have developed, survival is rare.

DIAGNOSIS

Prior to available accurate laboratory tests, a potentially infected animal was placed in isolation for observation. If it died a characteristic rabies death, the diagnosis was established. With the advent of the microscope in 1903, intracytoplasmic inclusion bodies were discovered in infected brain tissue by Aldelchi Negri, who at the time was an assistant of Camillo Golgi. These structures were subsequently called Negri bodies. In the 1980s the direct fluorescent antibody (DFA) test was formed, which remains to this day the diagnostic gold standard (Figure 192.1). For postmortem diagnosis in animals, fresh unfixed brain tissue is necessary for DFA testing as fixed tissue with agents such as formalin may yield inaccurate results. Brain tissue is the only sample tissue type for diagnosis as saliva and salivary gland excretion of the virus can be intermittent. The predictive value of a negative brain DFA test is 100%.

Routine laboratory tests and diagnostic studies are of little value in the diagnosis of rabies. Examination of the cerebrospinal fluid (CSF) may show leukocytosis, but protein and glucose assays are often normal. Antibodies to the virus in an unvaccinated patient with encephalitis confirms the diagnosis. In addition, saliva samples can be cultured and then tested for viral nucleic acid. A tissue diagnosis can be made in premortem humans using the DFA test on a skin sample from the back of the neck. Polymerase chain reaction (PCR) can also be used in diagnosis, but DFA is still considered the gold standard as PCR is hampered by obtaining universal *Lyssavirus* primers. Due to the ability to detect low copy numbers of viral nucleic acid, rapid turnaround time, and falling costs, it is likely that PCR-based techniques may become a viable diagnostic test in the near future.

In 2006, the CDC reported a case of encephalitis in a 15-year-old girl from Wisconsin who was bitten by a bat. Antibody titers to rabies virus were found in CSF and serum. She survived the infection. Another young boy developed encephalitis of undetermined etiology that progressed rapidly. He developed rabies-specific immunoglobulin G antibodies in increasing titers. Rabies virus could not be detected in the CSF by PCR; however, antibodies to the rabies virus were present.

Magnetic resonance imaging (MRI) changes most likely occur in the early stages of the infection. More extensive involvement of various regions of the brain has been shown in advanced stages on serial imaging. There are no specific features that are attributable to the rabies virus. Patients with acute rabies encephalitis have T2 hyperintense lesions in the brainstem, thalami, temporal cortex, hippocampus, and subcortical white matter. Mild signal changes can also be seen in the spinal cord and nerve roots corresponding to the site of injury of some patients. Enhancement with gadolinium contrast is not present until the patient is comatose.

TREATMENT

Treatment efforts are concentrated on preventing and treating complications of established infection and protecting those who come in contact with the patient from virus exposure. Neither vaccine nor rabies immunoglobulin increases survival in symptomatic patients and should be avoided. Attempts to treat symptomatic patients infected with dog rabies with therapeutics and intensive care support are usually unsuccessful.

A few patients who survived infection with good functional recovery had evidence of an early immune response to rabies virus in blood and CSF, with absence of virus in biologic fluids or hair follicles. Thus, a good outcome likely depends on a prompt host response in eradication of virus. Steroids should also be avoided in the treatment of cerebral edema if it develops. Universal precautions should be followed by hospital staff, and respiratory precautions are recommended for suctioning. Postexposure prophylaxis is recommended for contacts who were bitten or had clear contamination of mucous membranes to the patient's saliva, urine, or other body tissue.

Symptomatic treatment

Benzodiazepines, barbiturates, ketamine, or intravenous morphine may be used for treatment of the pharyngeal spasms. However, impairment of consciousness to the extent that ventilatory support is needed should be avoided. Autonomic symptoms should be monitored and treated.

Postexposure prophylaxis

Once an individual is bitten by an animal presumed to have rabies, it is vital to immediately begin the immunization. Raccoons, skunks, foxes, and coyotes are most often infected with the rabies virus. Patients exposed to these animals should receive postexposure prophylaxis as soon as possible. Transmission of rabies virus can occur from minor, even unrecognized, bites from bats. Therefore, rabies postexposure prophylaxis is recommended for all persons with bite, scratch, or mucous membrane exposure to a bat and should be considered if the history indicates that a bat was physically present, even if the person is unable to reliably report contact that could have resulted in a bite. An unprovoked attack by a domestic animal is more likely than a provoked attack to indicate that the animal is rabid. If the animal has been vaccinated, it is unlikely to be infected; if not vaccinated but otherwise healthy, the animal should be confined and observed for 10 days. Any illness during this time should be evaluated by a veterinarian and the public health department. Vaccination can be withheld if the animal remains healthy during this time. Small rodents (e.g., squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice) and lagomorphs (including rabbits and hares) are almost never infected with the virus and have not been known to transmit rabies to humans. Large rodents such as woodchucks are sometimes infected. Therefore, in cases involving rodent exposure, the state or local health department should be consulted before initiating prophylaxis. Postexposure therapy for rabies is highly effective, and no failures have been recorded in patients who have received all three arms of treatment. Failures have occurred only on deviation from the recommended protocol.

Local wound care

The abraded skin after a bite must be cleaned by soap and water or povidone-iodine solution. Even scratches or contaminated skin from saliva should be cleaned the same way. It has been found that cleaning the wound would help reduce the chances of developing rabies. There are no areas that are deemed more susceptible after a bite. All bites in any area should be treated with the same level of care. Tetanus prophylaxis and antibiotics may be necessary to prevent secondary infection.

Vaccination

Postexposure therapy includes both passive immunization with rabies immune globulin (RIG) and active immunization with the vaccine in those who have not been vaccinated previously. RIG is administered as a one-time dose and should be given within the first 7 days of the vaccine because after this time period the vaccine production of antibody is thought to have occurred. The recommended dose of RIG is 20 IU/kg body weight for any age group. It is typically administered around the bite wound. The RIG and vaccine should not be given at the same site. Vaccine alone is indicated in persons who have had pre-exposure prophylaxis with a cell culture vaccine series or who had been vaccinated with other types of rabies vaccine with a documented neutralizing antibody response.

In the United States, there are currently two Food and Drug Administration (FDA)-approved vaccines. The human diploid cell vaccine (HDCV), trade name Imovax, and the purified chick embryo cell vaccine (PCEC), trade name RabAvert, which are both administered intramuscularly (IM). Outside the United States, there are a purified vero cell rabies vaccine (PVRV) and a purified duck embryo vaccine available in addition to the HDCV and PCEC vaccines.

The vaccine should be given as a 1.0 mL IM injection in the deltoid area (the outer thigh may be used in younger children, but vaccine should not be given in the gluteal area) on days 0, 3, 7, and 14 according to CDC guidelines. All of these vaccines are used for both pre-exposure and post-exposure prophylaxis. The WHO still recommends a five-dose immunization (with an additional dose on day 28) in cases of higher exposure and both the WHO and CDC recommend five doses in immunocompromised individuals.

HDCV is the most expensive rabies vaccine but PCEC and PVRV are just as efficacious and safe and can be administered at lower doses intradermally in resource-limited settings. Older vaccines that are produced in sheep, goat, or mouse nervous tissue have unreliable potency and a high incidence of neurologic complications but are still used in some developing countries as they are cheaper.

Pre-exposure vaccination

Pre-exposure prophylaxis should be offered to persons at high risk for exposure to rabies. Persons who work with rabies virus in research laboratories or vaccine-production facilities are at highest risk for exposure and should have rabies antibody titers checked every 6 months. Other laboratory workers (e.g., those performing rabies diagnostic testing), spelunkers, veterinarians and staff, and animal-control and wildlife officers in areas where animal rabies is enzootic should also have antibody measurements done every 2 years. Booster doses (IM or ID) of vaccine should be administered to maintain an adequate serum titer. The immunization practices advisory committee (ACIP) recommends three pre-exposure doses of the HDCV given IM at 0, 7, and 21 or 28 days. This ensures both seroconversion and adequate duration of protective antibody. Routine serologic testing after vaccination is not needed as seroconversion has been uniform. Patients who are immunosuppressed or taking medications such as chloroquine, which may interfere with antibody response to the vaccine, should postpone pre-exposure vaccinations and consider avoiding activities for which rabies pre-exposure prophylaxis is indicated. When this is not possible, they should be vaccinated and their antibody titers checked.

EDUCATION

Prevention is the best cure. Knowledge is extremely vital in this disease. People should be informed of preventative measures if they are considered to be a high-risk group. The CDC has immensely resourceful web-based information for individuals who have concerns or common questions related to a dog bite. They have recommendations for people who would like to have a dog or cat as a household pet. Casual handshaking or standing next to someone who may be infected are not considered to be risks for acquiring the infection. Changing bed linen from an infected individual does not pose a threat, either. Certain risks seen in the domestic setting, barring animal bites, would also be from sexual activity, sharing utensils or cigarettes, and saliva contact from an infected source (CDC). A healthy person undergoing postexposure prophylaxis (PEP) does not constitute a potential threat for infecting others. If a person is found to be infected, the local health department should be notified once the infection is documented. In an unknown case of encephalitis, especially in children, a history must be ascertained about recent animal bites. Patients may not recognize that certain animals can be a threat for a rabies virus infection.

As there is currently no cure for rabies infection once it has reached the CNS, determining a definitive, positive diagnosis does not aid the patient directly. However, it is an important part of the workup and differential for acute encephalitis in that a negative result points toward a different cause for the encephalitis. Alternatively, a positive result is important from a public health perspective and garners patient isolation a necessity. It also aids in establishing a more detailed history for possible exposure in other family members.

193. Varicella-zoster virus

Jeffrey M. Weinberg

Varicella-zoster virus (VZV) is a member of the herpesviruses family, and is the etiogic agent of varicella and varicella zoster. Varicella, the exanthem caused by primary infection with VZV, generally occurs in childhood. Shingles, the clinical syndrome of segmental, unilateral, exanthem, and neuralgic pain due to reactivation of latent VZV infection, usually occurs many years after the primary infection. In the immunodeficient person, both primary and reactivated VZV infection can lead to severe generalized virus dissemination, the life-threatening form of VZV infection. The availability of antiviral agents for management of VZV infection has raised the importance of recognizing this infection in high-risk groups. Prior to the introduction of the VZV vaccine in the United States in 1995, approximately 4 million cases of chickenpox occurred each year, 83% in children younger than 9 years. The association between aging and VZV vulnerability is apparent in the epidemiology of the disease: of the estimated 1 million cases of herpes zoster in the United States each year, approximately 50% occur in individuals aged 50 years or older. A VZV vaccine was approved in 2006 for the prevention of shingles.

CLINICAL PRESENTATION

Varicella (chickenpox)

In healthy unvaccinated children, VZV infection manifests as a vesicular exanthem often associated with prodromal malaise, pharyngitis, rhinitis, and abdominal pain. The rash generally appears 15 days after VZV exposure; the range is 10 to 21 days. The vesicular eruption emerges in successive crops over the first 3 to 4 days of illness, usually with concomitant enanthem. Each skin vesicle appears on an erythematous base, resulting in the descriptive image of a dewdrop on a rose petal.

Figure 193.1 Varicella. Note various stages of lesions in each area of eruption. (Courtesy of David Schlossberg, MD.)

The eruption most commonly originates on the head and quickly progresses to the trunk, arms, and, finally, the legs. It is common to observe all cutaneous stages, including macules, vesicles, papules, and crusts, in the same area of the skin (Figure 193.1). Varicella often is associated with fever, headache, sore throat, or stomach ache. These symptoms may last for a few days, with fever in the 101°F to 102°F (38.3°C to 38.8°C) range. Primary VZV infection may involve the mucosal surfaces of respiratory, alimentary, and genitourinary systems, therefore those with varicella can have severe laryngitis, laryngotracheobronchitis, vaginitis, urethritis, pancreatitis, and enteritis. In immunocompromised individuals, severe abdominal pain or back pain can be an indicator of progressive VZV infection.

Varicella vaccine was licensed in the United States in 1995 for individuals ≥12 months of age. A second dose was recommended in the United States in June 2006. Since the introduction of the vaccine, the age-unadjusted incidence of

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

chickenpox has been approximately 3 cases per 1000 population, and the hospitalization rate for complications of varicella has decreased dramatically. Complications of varicella occur most frequently in those younger than 1 year and older than 15 years. These complications include bacterial superinfection of skin, dehydration, pneumonia, encephalitis, and hepatitis. With the availability of the vaccine, hospitalizations for chickenpox have significantly decreased and VZV-associated mortality is at an all-time low of less than 0.1 per million population.

Varicella zoster (shingles)

Although 10% to 20% of Americans overall will develop zoster in their lifetimes, 50% of persons reaching age 85 can be expected to do so; the incidence of herpes zoster rises dramatically, from a low of between 1.1 and 2.9 per 1000 person-years in people younger than 50 to 4.6 and 6.9 per 1000 person-years, respectively, in the age groups 50–59 and 60–69. The age groups 70–79 and $\geq$80 years old have the highest incidence, with 9.5 and 10.9 per 1000 person-years, respectively.

The principal risk factor for herpes zoster is prior history of VZV exposure. Any person who has had chickenpox or received the varicella vaccine as a child, which includes more than 90% of the US adult population, is at risk for herpes zoster. The association with advancing years, as previously described, is due to the age-related decline in VZV-specific cell-mediated immunity. Childhood zoster is rare but not unheard of, with cases reported in children as young as 4 months. The incidence of zoster in children younger than 10, however, is only 0.74 per 1000 person-years.

Immunocompromised people or those receiving immunosuppressive drugs are also at increased risk for zoster. Thus, human immunodeficiency virus (HIV) patients have a higher incidence of zoster disease than individuals with a healthy immune system, reported in one longitudinal study as 29.4 cases per 1000 patient-years. Patients undergoing bone marrow or organ transplant and treated with immunosuppressives are known to develop zoster with increased frequency.

Genetics may play a role in the development of herpes zoster, as suggested by the finding that elderly white men are four times more likely to develop zoster than elderly black men. Some reports have suggested that systemic steroid therapy can incite VZV reactivation as well, placing persons with conditions such as rheumatoid arthritis or lupus at increased risk. Finally, both trauma and stressful life circumstances have been suggested to play a role in development of herpes zoster, further increasing the population at risk.

The characteristic feature of herpes zoster is a vesicular rash of unilateral distribution limited to one to three adjacent dermatomes. The onset of the rash, however, often is preceded by a prodromal phase. Beginning 4 days to 2 weeks before lesions appear, patients often note pain and paresthesia in what will become the zoster-affected dermatome. The pain can be intermittent or continuous, and has been described by patients variously as throbbing, sharp, stabbing, burning, or shooting pain. Malaise, dysesthesia, and itching are frequent elements of the prodrome, as well.

The most common site of infection is the trigeminal nerve. Most patients exhibit thoracic distribution of zoster rash, with more than 50% of cases presenting with cutaneous lesions of the trunk. The rash generally appears proximally, then spreads distally along the affected dermatome. The initial lesions appear as erythematous maculopapules, which turn into vesicles within 12 to 24 hours. The vesicles become pustules in about 3 days, and form scabs 7 to 10 days later. New lesions generally appear over no more than 3 to 7 days, but the duration of the rash has been correlated with patient age (advancing age associated with longer duration) and site of infection (face healing more rapidly than other loci).

Zoster affecting the first division of the trigeminal nerve, as occurs in 10% to 15% of cases, can lead to herpes zoster ophthalmicus (HZO), which produces the characteristic zoster rash on the forehead, periocular area, and nose and can be accompanied by local pain. Ocular complications of HZO are among the most dangerous morbidity of zoster disease, placing patients at risk for sight impairment or vision loss due to nerve damage or ocular pathology.

Approximately 60% to 90% of zoster patients experience local neuritic pain and hypersensitivity in association with the acute herpetic rash. This pain is likely due to an immediate nociceptive response: local inflammation and tissue damage stimulate the primary afferent neurons of the skin and subcutaneous tissue, which neurologically manifests as pain. In addition, allodynia and hyperalgesia may be present, adding to patient discomfort during acute herpes zoster.

Pain associated with zoster disease resolves within several days for many patients, although

the degree of pain can be variable; one report has suggested that more extensive pain during the acute phase might predict the prolonged pain of postherpetic neuralgia (PHN), and another indicates that early pain therapy might limit the central development of chronic PHN pain following herpes zoster.

DIAGNOSIS

The features of varicella and varicella zoster are so characteristic that a diagnosis is generally made clinically. In chickenpox, lesions in all stages of development (macules, vesicles, pustules, and crusted lesions) may be a suggestive finding. The differential diagnosis of varicella includes the following: herpes simplex virus, Coxsackie and other enteroviruses, mycoplasma, streptococcal impetigo, rickettsialpox, insect bites, and allergic contact dermatitis.

For herpes zoster, the diagnosis can be made based on the presence of prodromal pain and/or itching, and the defining zoster rash. For patients presenting in the prodromal period, the pain and dysesthesia may require differentiation from other pain sources, such as trauma, myocardial ischemia, renal colic, gallbladder disease, or dental pain. Atypical lesions, furthermore, may require laboratory confirmation, which sometimes is obtained from viral culture (often difficult to recover from swabs) or more readily from direct immunofluorescence assay. Recently, nested and real-time polymerase chain reaction (PCR) testing of samples from skin lesions have proved valuable for identifying VZV, with more rapid amplification than other methods and high sensitivity. These laboratory techniques are most valuable for differentiating VZV from zosteriform herpes simplex, a herpes simplex viral infection that mimics zoster disease.

PREVENTION AND THERAPY

Varicella vaccine

The live, attenuated varicella vaccine (Varivax) was approved in the United States in 1995 and is recommended for persons older than 12 months. Every person in the United States who does not have indicators for VZV immunity should have two doses of varicella vaccine. The first dose should be administered at the age of 12 to 15 months. The second dose should be given between the ages of 4 and 6 years. People 13 years of age and older who have never had chickenpox or received chickenpox vaccine should get two doses, at least 28 days apart.

Each dose, for infants and adults, is 0.5 mL administered subcutaneously.

Other populations may benefit from varicella vaccine, including eligible healthcare and day-care workers, college students, prisoners, military recruits, nonpregnant women of childbearing age, and international travelers.

Prior to the introduction of the vaccine, about 11 000 people were hospitalized for chickenpox each year in the United States, and about 100 people died each year as a result of chickenpox in the United States. As noted previously, since the introduction of the vaccine, the incidence of chickenpox and the hospitalization rate for complications of varicella has decreased dramatically.

The vaccine is not recommended for infants <1 year old, for those on salicylate therapy, for pregnant women, or those allergic to components of the vaccine, including neomycin, gelatin, and monosodium glutamate. Immunosuppressed individuals should confer with their physician about the risks and benefits of vaccination.

Zoster vaccine

The herpes zoster vaccine is a live attenuated preparation of the Oka/Merck strain of VZV that boosts the recipient's immunity to VZV, thus increasing the chance that their latent VZV will remain dormant and that they will not develop herpes zoster. Its efficacy and safety in reducing the risk of herpes zoster disease in adults over age 60 were established in a pivotal trial, on the basis of which the US Food and Drug Administration (FDA) approved the vaccine in May 2006 for clinical use. On March 24, 2011, the FDA approved Zostavax for individuals 50 to 59 years of age.

Chickenpox

OVERALL ASSESSMENT

The goal in management is to treat the symptoms of primary VZV infection and to prevent complications if possible. The three stages of management are (1) establishing the likelihood of the diagnosis, (2) determining whether antiviral therapy is indicated, and (3) ruling out secondary bacterial infection, other complications, and failure of previous antiviral treatment.

SYMPTOMATIC THERAPY

Itching is the major symptom of chickenpox, and antipyretic management is important. Warm baths containing baking soda (1/3 cup per bathtub) or emulsified oatmeal (Aveno) can temporarily relieve pruritus. This can be combined with the oral administration of either diphenhydramine (Benadryl), 1.25 mg/kg every 6 hours, or hydroxyzine (Atarax, Vistaril), 0.5 mg/kg every 6 hours. In older children, cold pramoxine HCl 1% lotion with calamine 8% (Caladryl) can be used, but this should be avoided in infants because of the risk of excessive surface exposure and absorption of drug or vehicle (alcohol 2.2%). Fever should be controlled with acetaminophen, but salicylates should not be used because administration of certain salicylates to children with chickenpox increases the risk of subsequent Reye's syndrome. For severe dysuria, a cold compress on the genital area during urination will ease the pain and minimize the likelihood of a functional bladder obstruction.

ANTIVIRAL THERAPY

Acyclovir (Zovirax) is the only agent licensed in the United States for the treatment of chickenpox. It is indicated for treatment of chickenpox in certain normal persons, for disseminated VZV infection in immunosuppressed persons, and for treatment of shingles. Oral acyclovir should be used in otherwise healthy persons with chickenpox who are at risk for moderate to severe disease, such as those older than 12 years, those with chronic cutaneous or pulmonary disorders, those receiving chronic salicylate therapy, and those receiving short, intermittent, or aerosolized courses of corticosteroids or aerosolized corticosteroids (Table 193.1). The American Academy of Pediatrics (AAP) does not recommend that otherwise normal children younger than 12 years receive oral acyclovir for chickenpox.

All adults with chickenpox should receive oral acyclovir, and those with rapidly progressive infection should be treated with intravenous acyclovir. Valacyclovir (Valtrex) and famciclovir (Famvir), both of which are approved for treatment of shingles, are not approved in the United States for treatment of chickenpox. All immunosuppressed persons with chickenpox should be treated with intravenous acyclovir until the course of infection is defined. However, as noted by the AAP, some experts have used oral acyclovir in highly selected immunocompromised persons who are at relatively low risk for developing complications and in whom follow-up is assured. Case-by-case evaluation of risks versus benefits is necessary, but for many groups the risk of disseminating infection is sufficiently high and so unpredictable that intravenous treatment should be recommended in nearly all cases. Intravenous acyclovir should be used for the pregnant patient with serious complications of varicella, but, if acyclovir is used routinely for the pregnant woman with uncomplicated chickenpox, it should be recognized that the risk and benefits to the fetus and mother are mostly unknown. Varicella-zoster immune globulin (VZIG) is licensed for use in high-risk individuals at the time of exposure to VZV infection but is not recommended for treatment of chickenpox.

COMPLICATIONS

Pyoderma is the most frequently observed bacterial complication of varicella. It can be minimized by attention to good hygiene, including daily bathing with bacteriostatic soap or dilute bleach baths. Streptococcal and staphylococcal bacterial infections can be associated with bacteremia and subsequent osteomyelitis, with scarlet fever, and with bacterial synergetic gangrene.

Bacterial superinfection can affect the lower respiratory tract, producing pneumonia and bronchitis. Viral pneumonia is more likely to be a problem in older persons with chickenpox. Therefore, it is important to monitor pulmonary status during treatment.

It is important to monitor for gastrointestinal tract involvement, including bleeding and vomiting. Mild asymptomatic hepatitis is observed in a majority of children with varicella, usually asymptomatic elevation of hepatic enzymes for which no treatment is necessary. However, elevation of serum or urinary amylase may indicate pancreatitis, which may require supportive treatment. Although rare today, Reye's syndrome and other metabolic diseases must be considered in any child with varicella in whom there is vomiting and changes in mental status.

Neurologic complications include cerebral or cerebellar abnormalities; the latter is a more benign disease. Cerebellar ataxia, the most common syndrome associated with varicella encephalitis, is most often a benign entity due to postinfectious demyelination. There is no evidence that acyclovir treatment is necessary in postchickenpox cerebellitis, but it is prudent to include antiviral therapy in any cerebral presentation of VZV infection, especially if it may be

Table 193.1 Antiviral treatment of varicella-zoster virus (VZV) infection[a]

Agent	Indication	Creatinine clearance (mL/min/1.73 M^2)	Dose	Dosing interval	Duration (days)
Oral acyclovir	Chickenpox >age 12 yr	>25	20 mg/kg up to 800 mg	4 times/d	5
		10–25	Same	q8h	5
		0–10[b]	Same	q12h	5
	Shingles	>25	20 mg/kg up to 800 mg	5 times/d	5–7
		10–25	Same	q8h	5–7
		0–10[b]	Same	q12h	5–7
IV acyclovir	Life-threatening VZV infection	>50	500 mg/M^2 or 10 mg/kg[c,d]	q8h	7
		25–50	Same	q12h	7
		10–25	Same	q24h	7
		0–10[b]	250 mg/M^2	q24h	7
Famciclovir	Shingles >age 18 yr	>60	500 mg	q8h	7
		40–59	500 mg	q12h	7

		30–49	1000 mg	q12h	7
		10–29	1000 mg	q24h	7
		≤10	500 mg	q24h	7
Foscarnet	Acyclovir-resistant VZV[e]	>100[f]	60 mg/kg	q8h	7–10

[a] See package insert for recommended dose adjustment of all drugs.

[b] An additional dose is recommended after each hemodialysis treatment.

[c] To minimize renal toxicity an adequate urine output is required. This can be assured if the acyclovir is infused at a concentration of approximately 4 mg/mL over 1 hour and the same volume of fluid is given over the next hour.

[d] Use ideal body weight for height to calculate dose in obese person: M^2, square meter of body surface area.

[e] Foscarnet is recommended by experts for treatment of life-threatening acyclovir-resistant VZV infection, but this is not an US Food and Drug Administration (FDA)-approved indication for foscarnet use. Appropriate informed consent should be obtained before such use.

[f] Foscarnet is nephrotoxic, and dosage should be based on creatinine clearance. Guidelines for dosage adjustment are listed in the package information.

associated with continued viral replication such as in acquired immunodeficiency syndrome (AIDS) or other immunosuppressive states.

Bleeding disorders associated with varicella include disseminated intravascular coagulation, vasculitis, and idiopathic thrombocytopenic purpura (ITP). These should be managed according to conventional treatment, and there is no VZV-specific management regimen.

IMMUNOSUPPRESSED PATIENTS

As noted, acyclovir is the only indicated drug for the treatment of VZV infections in the immunosuppressed patient. These infections include disseminated chickenpox, disseminated shingles, or localized shingles. Three other antiviral medications, valacyclovir, famciclovir, and foscarnet (Foscavir), have activity against VZV. Valacyclovir and famciclovir are indicated for the treatment of shingles as described below (see Table 193.1). Foscarnet is recommended for the treatment of acyclovir-resistant VZV.

Shingles

OVERALL ASSESSMENT

The development of shingles in and of itself does not produce substantial morbidity; rather, it is the potential for neurologic and inflammatory complications of zoster disease that cause patients – and physicians – the greatest difficulty. The relationship between zoster infection and destruction of neurons and satellite cells has been well established, with neurologic damage beginning even before the characteristic zoster rash appears. PHN (Table 193.2), the most frequent complication of VZV, can cause debilitating pain and impaired quality of life among the otherwise healthy elderly. The associated pain, furthermore, can continue long after the rash resolves, despite aggressive antiviral and/or pain therapy.

SYMPTOMATIC THERAPY

Individuals with zoster should be instructed to keep the cutaneous lesions clean and dry to

Table 193.2 PHN can present with a range of neurologic features

- Pain can be intermittent or continuous, deep or superficial
- Pain described as throbbing or stabbing
- Spontaneous aching or burning
- Paroxysmal shooting pain
- Allodynia
- Hyperalgesia
- Intense itching

Adapted from Johnson and Whitton. *Expert Opin Pharmacother.* 2004;5:551–558.

reduce the risk of bacterial superinfection. A sterile, nonocclusive, nonadherent dressing placed over the involved dermatome will protect the lesions from contact with clothing. Acute pain can be very severe and refractory to therapy. Sympathetic-nerve blockade can provide rapid, temporary relief of severe pain. Scheduled short-acting narcotic analgesics can be prescribed. For persistent pain, long-acting, controlled-release are preferred. If the eye is involved, an ophthalmologist should be consulted for use of topical anti-inflammatory or antiviral medication and for long-term evaluation.

Treatment with corticosteroids may in the short term reduce herpes-related pain intensity, but it is associated with a risk of serious adverse effects. Longer-term studies have demonstrated that corticosteroids, administered orally or intrathecally, offer acute benefits but fail to prevent PHN. Corticosteroids may reduce pain intensity, but the high prevalence of diabetes, hypertension, and glaucoma among adults aged 50 years and older, those most likely to develop herpes zoster, severely limits the number of patients for whom corticosteroids would be helpful.

ANTIVIRAL THERAPY

Antiviral drugs have been consistently found to effectively reduce the severity and duration of herpes zoster, and are safe and well tolerated with minimal adverse effects. They do not, however, reliably prevent the development of PHN. Nearly all study protocols require initiation of antiviral therapy within 72 hours of rash onset. Although 72 hours is frequently mentioned as a cutoff for therapy, there are no data showing that antiviral therapy initiated more than 72 hours after rash onset is not helpful, and there are observational data to suggest that it is quite helpful.

Acyclovir, valacyclovir, and famciclovir are licensed in the United States for the treatment of shingles in otherwise normal persons (see Table 193.1). Acyclovir is the agent of choice for immunocompromised persons and is the only intravenous agent available for treatment of shingles. Valacyclovir is the prodrug of acyclovir and, because of better bioavailability, is preferred over acyclovir for oral therapy of shingles. Famciclovir is an oral prodrug of the antiviral agent penciclovir, which has potent activity against VZV, and famciclovir undergoes rapid biotransformation to the active antiviral compound. Safety and efficacy in children has not been established for either valacyclovir or famciclovir. Also, because of the potential for tumorigenicity in rats, famciclovir should not be given to pregnant or nursing mothers unless nursing is discontinued.

MANAGEMENT OF EXPOSURE TO VZV

The spread of infectious VZV from a person with chickenpox is by air droplets from nasopharyngeal secretions, which usually requires face-to-face exposure indoors for an hour but can also be via air currents to susceptible individuals without direct contact. The period of respiratory infectivity is generally considered to begin 48 hours prior to the onset of exanthem and to continue for 4 days after onset. In addition, the vesicular fluid can spread the virus by direct contact, so infectivity by contact with skin lesions is possible until they are crusted. Shingles can also spread by direct contact or by exposure to airborne infectious material. The incubation period for chickenpox following exposure to shingles is the same as for exposure to chickenpox – 15 days with a range of 10 to 21 days. The varicella attack rate in susceptible children on household exposure to chickenpox is approximately 90% and is 25% on exposure to household shingles.

IMMUNOCOMPROMISED HOST EXPOSED TO VZV

Prior to the introduction of the varicella vaccine, the only protection from VZV infection was passive immunization at the time of exposure. Families and school personnel must continue to be aware of exposure to VZV in high-risk persons so that VZIG can be administered within 96 hours. Any susceptible person at risk for complications of VZV (Table 193.3) should receive passive immunization if exposure was adequate to communicate disease and occurred within approximately 4 days.

Individuals receiving immunosuppressive therapy should have this discontinued during the incubation period, although this precaution

Table 193.3 Groups at risk for complications of VZV infection[a]

Susceptible persons on immunosuppressive therapy[b]
Persons with congenital cellular immunodeficiency
Person with an acquired immunodeficiency, including AIDS
Persons older than 20 years
Newborn infants exposed to onset of maternal varicella less than 5 days before or 2 to 7 days after birth
Premature infants weighing <1 kg[c]

[a] Susceptible (antibody negative) persons exposed to VZV by indoor face-to-face contact with an infected person less than 2 days before or anytime during vesiculopustular stage of chickenpox are at highest risk and should receive VZIG.

[b] All cytoreductive chemotherapy and radiotherapy is considered immunosuppressive. The immunosuppressive dose of prednisone equivalent can vary in individual cases but is in the range of 1 to 2 mg/kg/d.

[c] The risk of complications of VZV infection in this group, which is poorly defined, is based on the likelihood of protective maternal antibody versus gestational age at birth.

Abbreviations: VZV = varicella-zoster virus; AIDS = acquired immunodeficiency syndrome; VZIG = varicella-zoster immune globulin.

is waived if the underlying disease requires continued treatment. Although not approved for such use, especially in children ≤12 years, valacyclovir, given at a dose of 1000 mg orally three times daily or 500 mg in those weighing less than 40 kg, can be effective in settings of acute exposure to VZV to prevent the development of chickenpox.

NORMAL ADULTS EXPOSED TO VZV

More than 90% of adults have had VZV. Susceptible adults are at risk for life-threatening chickenpox, and they are the source of unexpected epidemics. The decision to use VZIG in susceptible healthy adults following close exposure to VZV should be made on an individual basis, taking into consideration the person's health, the type of exposure, and the likelihood of previous chickenpox.

NOSOCOMIAL VZV

Control of nosocomial infections requires three actions: (1) routine continuous surveillance of VZV susceptibility among hospital staff, with VZV vaccination as indicated; (2) adequate isolation of contagious VZV infections; and (3) rapid evaluation of and response to exposure. Hospitals that care for immunodeficient children should screen staff at the time of employment for susceptibility. This can be done efficiently by performing antibody tests on those who have a negative or unknown history of chickenpox. Susceptible employees should be vaccinated and excluded from care of patients with VZV infection until approximately 1 month after the second dose of vaccine. Exposed susceptible healthcare workers should be furloughed from the eighth day after initial exposure until 21 days after the last exposure.

If the VZV exposure is from a patient, he or she should be discharged if possible. If not possible, the patient should be placed in isolation designed to prevent spread of infection by both air and direct contact. Isolation should remain in effect until skin lesions are crusted.

After control of the source of infection comes quick assessment of three types of information: (1) the nature of the exposure and whether it is likely to result in secondary infections, (2) the susceptibility to VZV of the exposed patients or staff, and (3) the risk for complications in these exposed patients. Thus, the initial step is to define the hospital areas in which a definitive VZV exposure has occurred and then to focus on which patients in these areas are at risk for infection. Those patients remaining in the hospital should be placed in respiratory isolation between days 8 and 21 postexposure or for 8 to 28 days for those receiving VZIG.

MANAGEMENT OF THE PREGNANT WOMAN

A syndrome of congenital varicella consisting of low birth weight, cutaneous scarring, limb hypoplasia, microcephaly, and other brain and eye abnormalities can occur in the baby of a pregnant woman who has chickenpox. Teratogenic damage results only from first- and second-trimester infection, and clinically apparent disease occurs only in approximately 2% of infants born after maternal varicella in early pregnancy. For this reason, experts advise that maternal chickenpox is not a medical indication for abortion. There is no reliable diagnostic method, including amniocentesis and ultrasound, for determining teratogenic intrauterine infection. VZIG should be offered to pregnant, varicella-seronegative women with significant exposure to VZV infection. Oral antiviral prophylaxis should be considered for susceptible pregnant women exposed to VZV who did not receive VZIG or have risk factors for severe disease. Intravenous acyclovir should be given to pregnant women who develop complicated varicella at any stage of pregnancy. However, it is generally recommended that these agents be used only if the benefit to the pregnant woman clearly exceeds the potential risk to the fetus.

ACKNOWLEDGMENT

I would like to acknowledge Dr. John A. Zaia for this update to his prior version of this chapter.

194. Viral hemorrhagic fevers

Daniel G. Bausch

INTRODUCTION

The term *viral hemorrhagic fever* (VHF) refers to an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock. VHFs are caused by small, single-stranded, lipid-enveloped RNA viruses from four families (Table 194.1).

EPIDEMIOLOGY

Natural maintenance and transmission to humans

With the exception of dengue virus (see Chapter 183, Dengue), for which humans can now be considered to be the reservoir, hemorrhagic fever viruses are zoonotic and maintained in nature in mammals (Table 194.1). The endemic area of any given VHF is thus restricted by the distribution of its natural reservoir and/or arthropod vector, although the distribution of the virus and disease are often less vast than that of the reservoir. Infection is presumed to most often result from inadvertent inoculation of virus-contaminated reservoir excreta into mucous membranes or broken skin or, in the case of the arbovirus VHFs, mosquito or tick bite. Aerosol transmission has been suggested but there are few data to confirm or refute this route of exposure and empiric field observations suggest that aerosol transmission is not a predominant mode of spread, if it occurs at all. Nevertheless, artificially produced aerosols can infect laboratory animals, with obvious implications for potential use as bioweapons.

Human-to-human transmission

Secondary human-to-human transmission occurs in many VHFs, usually through direct contact with contaminated blood or body fluids (Table 194.1), although secondary attack rates are generally low (15%–20%). Infection probably occurs most often through oral or mucous membrane exposure. Again, there are few data on aerosol spread. Large outbreaks are almost always the result of amplification in healthcare settings in which basic infection control measures have broken down, usually in areas of extreme poverty or civil strife. The risk of transmission during the incubation period or from asymptomatic persons is negligible, although a case of Argentine hemorrhagic fever was reported due to blood transfusion from a donor who was asymptomatic. Although rare, sexual transmission during early convalescence has been suspected, best documented for Ebola, Marburg, Lassa, and Junín viruses. Despite the ease of modern-day travel, imported VHF cases remain extremely rare.

PATHOLOGY AND PATHOGENESIS

Microvascular instability, increased vascular permeability, and impaired hemostasis are the pathophysiologic hallmarks of VHF, although the mechanisms vary with each virus. Mortality usually results not from exsanguination but from a process akin to septic shock, with insufficient effective circulating intravascular volume leading to cellular dysfunction and multiorgan system failure. In fact, external bleeding is seen in a minority of cases of some VHFs (Table 194.2).

After inoculation, virus typically replicates in dendritic cells before disseminating to regional lymph nodes and then through the lymph and blood monocytes to a broad array of organs, including liver, spleen, lymph node, adrenal gland, lung, and endothelium. The particular organs most affected vary with the VHF (Table 194.2). Virus interaction with immune cells, especially macrophages and endothelial cells, results in cell activation and the unleashing of an inflammatory vasoactive process consistent with the systemic inflammatory response syndrome. Impaired hemostasis may entail endothelial cell, platelet, and/or coagulation factor

Dengue	Dengue HF	Tropics and subtropics worldwide	Human/mosquito (*Ae. aegypti* and *Ae. albopictus*)	100 000–200 000[i]	1:10–100 depending on age, previous infection, genetic background, and infecting serotype	None
Omsk HF	Omsk HF	Western Siberia	Rodent/tick (primarily *Dermacentor* and *Ixodes* species)	100–200	Unknown	Not reported
Kyasanur Forest disease	Kyasanur Forest disease	Karnataka state, India; Yunnan Province, China; Saudi Arabia	Vertebrate (rodents, bats, birds, monkeys, others)/tick (*Haemophysalis* species and others)	~500	Unknown	Not reported, but laboratory infections have occurred
Alkhumra HF[j]	Proposed name: Alkhumra HF	Saudi Arabia, Egypt	Ticks?	≤50	Unknown	Not reported

Abbreviation: HF = hemorrhagic fever.

[a] Six species or subtypes of Ebolavirus are recognized with varying associated case-fatality ratios (see Table 194.2). All are endemic to sub-Saharan Africa, with the exceptions of Reston ebolavirus that is found in the Philippines and Lloviu ebolavirus which was detected in bats in Spain.

[b] Although some endemic transmission of the filoviruses (Ebolavirus>Marburgvirus) and Rift Valley fever virus occurs, these viruses have most often been associated with outbreaks. Filovirus outbreaks are typically less than 100 cases and have never been greater than 500.

[c] The virus families Arenaviridae and Bunyaviridae are serologically, phylogenetically, and geographically divided into Old World (i.e., Africa) and New World (i.e., the Americas) complexes.

[d] In addition to the arenaviruses listed in the table, Flexal and Tacaribe viruses have caused human disease as a result of laboratory accidents. Another arenavirus, Whitewater Arroyo, has been noted in sick persons in California but its role as a pathogen has not been clearly established.

[e] Discovered in 2008. Only 5 cases (4 of them fatal) from one outbreak have been noted. The index case came to South Africa from Zambia.

[f] Discovered in 1990. Only 3 cases (1 fatal) have been noted, 2 of them from laboratory accidents.

[g] Discovered in 2003 from a small outbreak from which blood was obtained from one fatal case and Chapare virus isolated. Few other details have been reported.

[h] Although Rift Valley fever virus can be found throughout sub-Saharan Africa, large outbreaks usually occur in East Africa's Rift Valley region.

[i] Based on estimates from the World Health Organization. Significant underreporting occurs. Incidence may fluctuate widely in place and time.

[j] Alkhumra is considered by some to be a variant of Kyasanur Forest disease virus. Disagreement exists over the proper spelling of the virus, written as "Alkhurma" in some publications.

Table 194.2 Clinical aspects of the viral hemorrhagic fevers

Disease	Incubation period (days)	Onset	Bleeding	Rash	Jaundice	Heart	Lung	Kidney	Central nervous system	Eye	Case fatality ratio	Clinical management

Dengue HF	3–15	Abrupt	++	+++	+	++	+	0	+	0	Untreated: 10–15% Treated: ≤1%	Supportive
Omsk HF	3–8	Abrupt	++	0	0	+	++	0	+++	+	1%–3%	Supportive
Kyasanur Forest disease	3–8	Abrupt	++	0	0	+	++	0	+++	+	3%–5%	Supportive
Alkhumra HF[g]	3–8	Abrupt	++	+	+	+	+	0	++	+	20%–25%	Supportive

Abbreviations: ECMO = extracorporeal membrane oxygenation; HF = hemorrhagic fever.

[a] Six species or subtypes of Ebolavirus are recognized with varying associated case-fatality ratios: Zaire – 85%, Sudan – 55%, Bundibugyo – 40%, Tai Forest (also called Cote d'Ivoire) – 0 (only one recognized case, who survived), Reston – 0 (not pathogenic to humans), Lloviu – no human infections recognized.

[b] The case fatality ratio was 22% in the first recognized outbreak of Marburg HF in Germany and Yugoslavia in 1967 but has been consistently over 80% in outbreaks in central Africa where the virus is endemic. Possible reasons for this discrepancy include differences in quality of care, strain pathogenicity, route and dose of infection, underlying prevalence of immunodeficiency and comorbid illnesses, and genetic susceptibility.

[c] A morbilliform or maculopapular skin rash almost always occurs in persons with lighter skin, who are usually expatriates, but, for unclear reasons, is rarely present in darker-skinned Africans from the endemic area.

[d] Data are insufficient to distinguish between the syndromes produced by the various arenaviruses found in the Americas. They are thus frequently grouped as the "South American hemorrhagic fevers."

[e] HF, encephalitis, and retinitis may be seen in Rift Valley fever independently of each other.

[f] The incubation period of Crimean-Congo HF varies with the mode of transmission: typically 1–3 days after tick bite and 5–6 days after contact with infected animal blood or tissues.

[g] Based on preliminary observations. Fewer than 100 cases have been reported.

Key: 0 = sign not typically noted/organ not typically affected, + = sign occasionally noted/organ occasionally affected, ++ = sign commonly noted/organ commonly affected, +++ = sign characteristic/organ involvement severe.

dysfunction. Disseminated intravascular coagulation (DIC) is frequent in some VHFs (Table 194.2). The degree of tissue damage varies with the VHF and may be mediated either through necrosis or apoptosis. Cardiac inotropy may be inhibited in some VHFs, further impairing organ perfusion. Adrenal or pituitary gland necrosis with consequent vascular collapse has been postulated but not specifically demonstrated. Virus is cleared rapidly from the blood in survivors but may remain for weeks or months in a few immunologically protected sites, such as the chambers of the eye, central nervous system, and gonads, the latter resulting in the aforementioned sexual transmission during convalescence.

The pathogenesis of most VHFs appears to be related to unchecked viremia, with most fatal cases failing to mount a significant antibody response, in some cases due to virus-induced suppression of the host adaptive immune response. Virus can be found in a wide variety of body fluids during the acute illness, including blood, saliva, stool, and breast milk. Inflammatory cell infiltration is usually mild, consisting of a mix of mononuclear cells and neutrophils. However, in dengue, yellow fever, and hantavirus infections (see Chapter 186, Hantavirus cardiopulmonary syndrome in the Americas), in which viremia is usually cleared prior to the most severe phase of the disease, the host immune response may play a detrimental role. The unique process of antibody-mediated enhancement may facilitate the development of dengue hemorrhagic fever (see Chapter 183, Dengue).

CLINICAL PRESENTATION

VHF is seen in both genders and all ages. Although the clinical manifestations of each VHF may differ as disease progresses, distinction in the early phases is rarely possible. Most patients present with nonspecific signs and symptoms difficult to distinguish from other common febrile illnesses, including fever, general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, and lumbosacral pain (Table 194.2). The pharynx may be erythematous or even exudative, especially in Lassa fever, resulting in misdiagnosis of streptococcal pharyngitis or mononucleosis (Figure 194.1A). Conjunctival injection or hemorrhage is frequent but not typically accompanied by itching, discharge, or rhinitis (Figures 194.1B and C). Hiccups may be seen early in Ebola hemorrhagic fever. Gastrointestinal signs and symptoms ensue in the first few days, including nausea and vomiting, epigastric and abdominal pain and tenderness (especially in the right upper quadrant in Ebola hemorrhagic fever), and non-bloody diarrhea. Appendicitis or other acute abdominal emergencies are sometimes suspected, prompting potentially hazardous (in terms of risk of bleeding and nosocomial spread) surgical interventions. Morbilliform, maculopapular, petechial, or

ecchymotic skin rashes may be seen, depending on the specific VHF (Table 194.2 and Figure 194.1D). Hepatosplenomegaly is frequently noted but may simply represent high underlying prevalence in populations in sub-Saharan Africa where most clinical observations have been made. Relative bradycardia (Faget's sign) and orthostatic hypotension may be noted, especially in yellow fever and dengue virus infections. Biphasic illnesses are described with a quiescent period of days (yellow fever, dengue hemorrhagic fever, and Rift Valley fever) to weeks (Kyasanur Forest disease and Omsk hemorrhagic fever) after which the most severe manifestations may set in, but not uniformly noted. Distinct progressive phases of prodrome, hypotension, oliguria/renal failure, diuresis, and convalescence are classically described for hemorrhagic fever with renal syndrome (HFRS), but again not uniformly seen. Neck pain and stiffness, retro-orbital pain, and photophobia and other meningeal signs are common in Rift Valley fever, Kyasanur Forest disease, and Omsk hemorrhagic fever.

In severe cases, patients progress towards the end of the first week of illness to vascular instability that may be manifested by facial flushing, edema, bleeding, hypotension, shock, and proteinuria (Figures 194.1E–H). The likelihood of hemorrhage varies with the VHF (Table 194.2) and may be manifested as hematemesis, melena, hematochezia, menometrorrhagia, petechiae, purpura, epistaxis, and bleeding from the gums and venipuncture sites (Figures 194.1E–G). Hemoptysis and hematuria are infrequent. Hemorrhage is almost never present in the first 48 hours of illness. Facial and neck swelling are classic signs of severe Lassa and Lujo virus infection. Central nervous system manifestations, including delirium, tremor, gait anomalies, convulsions, and hiccups may be noted in end-stage disease. Renal insufficiency or failure may occur, especially in HFRS. Pregnant women often present with spontaneous abortion and vaginal bleeding. A dry cough, sometimes with a few scattered rales on auscultation, is frequently noted, but prominent pulmonary symptoms early in the course of disease are uncommon, with the exception of with hantavirus pulmonary syndrome. With the exception of yellow fever, jaundice is not typical in the absence of underlying Gilbert's syndrome, drug reaction, or coinfection. Radiographic and electrocardiographic findings are generally nonspecific.

Disease usually progresses rapidly, with death 7 to 14 days after symptom onset in fatal cases. Common indicators of a poor prognosis include shock, bleeding, neurologic manifestations, high viremia (or surrogate measurements of antigen or genome copies), and elevated levels of aspartate aminotransferase (>150 IU/L). Maternal and fetal mortality are elevated in pregnancy, especially during the third trimester, where they approach 100%. However, mild and even asymptomatic cases have been reported even for what are considered the most virulent VHFs, possibly related to differences in route and dose of infection, underlying comorbid illness, and host genetic predisposition. Specific human genotypes or histocompatibility markers have been associated with risk of Lassa fever and hantavirus infection.

DIFFERENTIAL DIAGNOSIS

The nonspecific early clinical presentation makes clinical diagnosis difficult, with a long differential diagnosis (Table 194.3). Recognition of case clusters, often involving healthcare workers, is a common first clue. A detailed epidemiologic history and physical exam and preliminary laboratory results (Table 194.4) are critical, including details of travel, exposures, occupational risks, and disease progression (for example, timing of hemorrhage relative to onset of illness). VHF should be considered in patients who (1) reside in or traveled to an endemic area (Table 194.1); (2) had potential direct contact with blood or body fluids of someone with a VHF during their acute illness (this group most often is composed of healthcare workers, persons caring for family members at home or preparing bodies for burial, and laboratory personnel); (3) had contact with live or recently killed wild animals (especially nonhuman primates) in or recently arriving from an endemic area, including veterinarians, hunters, farm and abattoir workers, and taxidermists. Food potentially recently contaminated by these animals could also be a source of infection, although this remains to be clearly documented; (4) worked in a VHF research laboratory or animal facility; or (5) had sexual relations with someone recovering from a VHF in the last 3 months. Most VHFs are rare even in persons meeting the above criteria so alternative diagnoses, especially malaria and typhoid fever, should always be aggressively sought. Acts of bioterrorism must be considered if VHF is strongly suspected in a patient without any of the above criteria, especially if clusters of cases occur.

Table 194.3 Differential diagnosis of the viral hemorrhagic fevers

Disease	Distinguishing characteristics and comments
Parasites	
Malaria	Classically shows paroxysms of fever and chills; hemorrhagic manifestations less common; malaria smears or rapid test usually positive; coinfection (or baseline asymptomatic parasitemia) common; responds to antimalarials
Amebiasis	Hemorrhagic manifestations other than bloody diarrhea generally not seen; amebic trophozoites identified in the stool by microscopy and/or antigen assays; responds to antiparasitics
Giardiasis	Positive stool antigen test and/or identification of trophozoites or cysts in stool; responds to antiparasitics
African trypanosomiasis (acute stages)	Especially the east African form. Examination of peripheral blood smear/buffy coat may show trypanosomes
Bacteria (including Spirochetes, *Rickettsia*, *Ehrlichia*, and *Coxiella*)	
Typhoid fever	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Bacillary dysentery (including shigellosis, campylobacteriosis, salmonellosis, and enterohemorrhagic *Escherichia coli* and others)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; respond to antibiotics
Capnocytophaga canimorsus	Associated with dog and cat bites, typically in persons with underlying immunodeficiency, notably asplenic patients; responds to antibiotics
Meningococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; bleeding within the first 24–48 hours after onset of illness and rapidly progressive illness typical; large ecchymoses typical of meningococcemia are unusual in the VHFs except for Crimean-Congo HF; rapid serum latex agglutination tests can be used to detect bacterial antigen in meningococcal septicemia; may respond to antibiotics (critical to administer early)
Staphylococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; may respond to antibiotics
Septic abortion	History of pregnancy and positive pregnancy test
Septicemic or pneumonic plague	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; large ecchymoses typical of plague are unusual in the VHFs except for Crimean-Congo HF; pneumonic plague may mimic hantavirus pulmonary syndrome; may respond to antibiotics
Streptococcal or Epstein–Barr virus pharyngitis	May mimic the exudative pharyngitis sometimes seen in Lassa fever
Tuberculosis	Hemoptysis of advanced pulmonary tuberculosis may suggest VHF, but tuberculosis generally has a much slower disease evolution
Tularemia	Ulceroglandular and pneumonic forms more common; responds to antibiotics
Acute abdominal emergencies	Appendicitis, peritonitis, and bleeding upper gastrointestinal ulcer
Pyelonephritis and poststreptococcal glomerulonephritis	May mimic HF with renal syndrome
Anthrax (inhalation or gastrointestinal)	Prominent pulmonary manifestations and widened mediastinum on chest x-ray in inhalation form; responds to antibiotics
Atypical bacterial pneumonia (*Legionella*, *Mycoplasma*, *Chlamydia pneumoniae* and *Chlamydia psittaci*, others)	May mimic hantavirus pulmonary syndrome; exposure to birds; symptoms often not present until late in the illness in psittacosis; respond to antibiotics
Relapsing fever	Recurrent fevers and flu-like symptoms, with direct neurologic involvement and splenomegaly; spirochetes visible in blood while febrile; responds to antibiotics
Leptospirosis	Jaundice, renal failure, and myocarditis in severe cases; responds to antibiotics
Spotted fever group rickettsia (including African tick-bite fever, Boutonneuse fever, Rocky Mountain spotted fever)	Incubation period of 7–10 days after tick bite, compared with 1–3 days in Crimean-Congo HF; necrotic lesions (eschar) typically seen at site of tick bite in some rickettsial diseases while there may only be slight bruising at the bite site in Crimean-Congo HF; rash (if present) of rickettsial infection classically involves palms and soles

Table 194.3 *(continued)*

Disease	Distinguishing characteristics and comments
Q fever *(Coxiella burnetii)*	Broad spectrum of illness, including hepatitis, pneumonitis, encephalitis, and multisystem disease with bleeding; responds to antibiotics
Ehrlichiosis	Diagnosis by serology and PCR; blood film may be useful; responds to antibiotics
Viruses	
Influenza	Prominent respiratory component to clinical presentation; no hemorrhagic manifestations; influenza rapid test may be positive; may respond to anti-influenza drugs
Arbovirus infection (including dengue and West Nile fever)	Encephalitis unusual, but when present may mimic the VHFs with significant neurologic involvement (Kyasanur Forest disease, Omsk HF); usually less severe than VHF; hemorrhage not reported
Viral hepatitis (including hepatitis A, B, and E, Epstein–Barr, and cytomegalovirus)	Jaundice atypical in HF except yellow fever; tests for hepatitis antigens positive; fulminant infection resembling VHF may be seen in persons with underlying immune deficiencies
Herpes simplex or varicella-zoster	Fulminant infection with hepatitis (with/without vesicular rash); elevated transaminases and leukopenia typical; disseminated disease may be noted in otherwise healthy persons; poor response to acyclovir drugs unless recognized early
HIV/AIDS	Seroconversion syndrome or HIV/AIDS with secondary infections, especially septicemia
Measles	Rash may mimic that seen in early stages of some VHFs and may sometimes be hemorrhagic; prominence of coryza and upper respiratory symptoms in measles should help differentiate; vaccine preventable
Rubella	Rash may mimic that seen in early stages of some VHFs; usually a mild disease; vaccine preventable
Hemorrhagic or flat smallpox	Diffuse hemorrhagic or macular lesions; in contrast to the VHFs, the rash may involve the oral mucosa, palms, and soles; smallpox in the wild has been eradicated
Alphavirus infection (including chikungunya and o'nyong-nyong)	Joint pain typically a predominant feature
Fungi	
Histoplasmosis	Pulmonary disease may mimic hantavirus pulmonary syndrome; recent entry into mines or caves
Noninfectious etiologies	
Heat stroke	History for extreme heat exposure; absence of sweating; bleeding not typical but DIC may occur
Idiopathic and thrombotic thrombocytopenic purpura (ITP/TTP)	Presentation usually less acute than VHF; may have prominent neurologic symptoms in TTP; coagulation factors normal and DIC absent; often respond to corticosteroids (ITP) or plasma exchange (TTP)
Acute glaucoma	May mimic the acute ocular manifestations of Rift Valley fever
Hematologic malignancies (leukemia, lymphoma)	May resemble leukemoid reaction occasionally seen in HF with renal syndrome
Drug sensitivity or overdose	Stevens–Johnson syndrome and anticoagulant (warfarin) overdose
Industrial and agricultural chemical poisoning	Especially anticoagulants, although other symptoms of VHF absent
Hematoxic snake bite envenomation	History of snake bite

Abbreviations: AIDS = acquired immunodeficiency syndrome; DIC = disseminated intravascular coagulopathy; HF = hemorrhagic fever; HIV = human immunodeficiency virus; PCR = polymerase chain reaction; VHF = viral hemorrhagic fever.

LABORATORY DIAGNOSIS

Prompt laboratory confirmation of VHF is imperative but testing is unfortunately only available in a few specialized laboratories since no commercial assays exist, with the exception of various kits for dengue fever and hantavirus pulmonary syndrome. In the United States, testing can be arranged through the Centers for Disease Control and Prevention (phone 404–639–1115, after hours 770–488–7100; e-mail dvd-1spath@cdc.gov). Commonly used diagnostic assays include enzyme-linked immunosorbent assay (ELISA) for viral antigen and IgM antibody, polymerase chain reaction, virus culture, immunofluorescent antibody assay, and

Table 194.4 Indicated laboratory tests and characteristic findings in the viral hemorrhagic fevers

Test	Characteristic findings and comments
Leukocyte count	Early: moderate leukopenia (except for hantavirus infection, in which early leukocytosis with immunoblasts are classically noted); later: leukocytosis with left shift; granulocytosis more suggestive of bacterial infection
Hemoglobin and hematocrit	Hemoconcentration (especially noted in hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome)
Platelet count	Mild-to-moderate thrombocytopenia
Electrolytes	Sodium, potassium, and acid–base perturbations, depending upon fluid balance and stage of disease Often increased
BUN/creatinine	Renal failure may occur late in disease
Serum chemistries (AST, ALT, amylase, gamma-glutamyl transferase, alkaline phosphatase, creatinine kinase, lactate dehydrogenase, lactic acid)	Usually increased, especially in severe disease; AST > ALT; a lactate level greater than 4 mmol/L (36 mg/dL) may indicate persistent hypoperfusion and sepsis. Lactate dehydrogenase is typically markedly increased in hantavirus pulmonary syndrome
Sedimentation rate	Normal or decreased
Blood gas	Metabolic acidosis may be indicative of shock and hypoperfusion
Coagulation studies (PT, PTT, fibrinogen, fibrin split products, platelets, D-dimer)	DIC common in Ebola, Marburg, Lujo virus, Crimean-Congo HF, and New World arenavirus infections. D-dimers appear to be an especially early and sensitive indicator
Urinalysis	Proteinuria common; hematuria may be occasionally noted; sediment may show hyaline-granular casts, and round cells with cytoplasmic inclusions
Blood culture	Useful early to exclude VHF and later to evaluate for secondary bacterial infection; blood should be drawn before antibiotic therapy is instituted
Stool culture	Useful to exclude VHF (in favor of hemorrhagic bacillary dysentery)
Thick and thin blood smears	May aid in the diagnosis of blood parasites (malaria and trypanosomes), bacterial sepsis (meningococcus, capnocytophaga, and anthrax) and ehrlichiosis; all negative in VHF unless coinfection
Rapid test, PCR, or other assay for malaria	Negative in VHF unless coinfection with malaria

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase; DIC = disseminated intravascular coagulation; VHF = viral hemorrhagic fever; BUN = blood urea nitrogen; PT = prothrombin time; PTT = partial thromboplastin time; PCR = polymerase chain reaction.

immunohistochemistry on postmortem tissues. Research is underway on a variety of new diagnostic approaches.

CLINICAL MANAGEMENT

Patients should generally be treated in an intensive care unit. For most VHFs, only supportive therapy is available. Treatment guidelines generally follow those recommended for septic shock, given the overlap in the pathogenesis of that condition and severe VHF, and considering that results from controlled trials on VHF are rare. Consultation with infectious disease specialists with experience treating VHF should be sought as soon as the diagnosis is considered. The process of performing a workup for non-VHF etiologies while assuring staff and patient safety and avoiding undue panic is a delicate one. Knowledge that most VHFs are rare and that routinely practiced universal and contact precautions are protective in the vast majority of cases should offer reassurance. Confirmed cases of VHF should be reported immediately to government health authorities.

Fluid management

Fluid management in VHF poses a particular challenge. Severe microvascular instability, often complicated by vomiting, diarrhea, decreased fluid intake, and third-spacing, often dictates aggressive fluid replacement, which may prevent shock and DIC. However, overaggressive and unmonitored rehydration may lead to pulmonary edema, especially given the impaired cardiac

function present in some VHFs, particularly hantavirus pulmonary syndrome. Although invasive hemodynamic monitoring would seem to be in order, with the exception of peripheral intravenous lines, indwelling vascular devices are contraindicated due to the risk of bleeding at the site, although they have been occasionally placed without reported complications. Intramuscular and subcutaneous injections should be avoided due to the risk of hematoma. It is probably best to rely on frequent sphygmomanometer readings and fluid balance assessment from capillary refill and urine output.

Early goal-directed therapies have been shown to mitigate both mortality and organ dysfunction in shock. Crystalloids (normal saline or Ringer's lactate), blood products (see below), and, if necessary, vasopressors (norepinephrine, adding epinephrine when warranted) should be infused to maintain mean arterial blood pressure above 65 mm Hg in adults. Vasopressin (0.03 U/min) can be added to decrease the norepinephrine dose but should not be used as the initial vasopressor. Dobutamine should be considered if there is evidence of myocardial dysfunction but dopamine is not recommended. Peritoneal and hemodialysis have been employed extensively in patients with HFRS without frequent complications, but there is little published experience with the other VHFs. Specific World Health Organization (WHO) guidelines exist for the fluid management of dengue shock syndrome (see Chapter 183).

Blood products and management of DIC

Despite profuse bleeding in some VHFs (Table 194.2), blood products should not be given empirically but rather only to meet defined clinical and laboratory parameters in the face of clinically significant hemorrhage. Transfusions, preferably with packed red blood cells, should be used to maintain a hemoglobin over 7.0 g/dL while avoiding volume overload, taking into account that chronic anemia due to malaria and malnutrition may be frequent in patients in certain geographic areas. Whole blood may be substituted if packed cells are not available. Transfusion of platelet concentrate (1–2 U/10 kg) and/or fresh frozen plasma (FFP) (15–20 mL/kg) may be required if DIC is present (Table 194.2). Treatment should not be based on laboratory results alone except in preparation for an invasive procedure or when platelet levels fall to dangerously low levels (<50 000/mm^3 in a bleeding patient or 20 000/mm^3 without bleeding). The platelet count should generally rise by at least 2000/mm^3 per unit of platelets transfused, although the response will be less if there is ongoing DIC and platelet consumption. Impaired platelet aggregation may promote hemorrhage in some VHFs, especially Lassa fever, even when platelet counts are not drastically low. Fibrinogen concentrate (total dose 2–3 g) or cryoprecipitate (1 U/10 kg) may be administered instead of FFP, although FFP has the theoretical advantage of containing all coagulation factors and inhibitors deficient in DIC but no activated coagulation factors. Vitamin K (10 mg intravenous or orally for 3 days) and folic acid may be given, especially if underlying malnutrition or liver disease is suspected, although their efficacy is unknown.

Oxygenation and ventilation

With the exception of hantavirus pulmonary syndrome, for which early mechanical ventilation is often lifesaving, impaired gas exchange is not typically a prominent feature of VHF, especially in the early phases of disease and in the absence of iatrogenic pulmonary edema. Most patients can be supported with oxygen administered via a nasal cannula or face mask. In neurologically intact patients, noninvasive positive pressure ventilation may be a useful adjunct to forestall intubation. When mechanical ventilation is required, lung-protective tidal volumes (6–8 mL/kg of ideal body weight) should be employed to avoid ventilator-induced lung injury (i.e., barotrauma) and pulmonary hemorrhage. Extracorporeal membrane oxygenation has been used with apparent benefit in hantavirus pulmonary syndrome. Due to the risk of bleeding, arterial puncture for blood gas determination should be minimized, relying on respiratory rate and pulse oximetry if possible.

Antiviral drugs

The guanosine analog ribavirin is the only currently available antiviral therapy for any VHF (Table 194.2). Early treatment is imperative for maximum benefit. The best data are for the arenaviruses, especially Lassa fever, and HFRS (Table 194.2). Ribavirin also appears to be efficacious in Crimean-Congo HF, although few randomized controlled clinical trials have been performed. A prospective trial of ribavirin in

Rift Valley fever in Saudi Arabia in 2000 was stopped after an increase in encephalitis was noted in the treatment group, but significant baseline discrepancies between the treatment and control groups make definitive conclusions difficult. In vitro data generally show activity of ribavirin against dengue, yellow fever, and Omsk hemorrhagic fever viruses, but clinical studies have not been performed. Ribavirin is not efficacious against Ebola or Marburg viruses. The main side effects of intravenous ribavirin are a mild-to-moderate hemolytic anemia, which infrequently necessitates transfusion and disappears with cessation of treatment, and rigors when the drug is infused too rapidly. A number of experimental therapies have shown in vitro activity and therapeutic benefit in animal studies and have been used on a compassionate-use basis in humans, but are not yet approved or widely available.

Convalescent plasma and antibody therapy

Although cellular immunity is thought to be the primary arm of protection in most VHFs, treatment with convalescent immune plasma has often been tried, especially for arenavirus infections. Transfusion of appropriately titered convalescent plasma within the first 8 days of illness reduces the case fatality of Argentine hemorrhagic fever to less than 1%. However, this therapy has been associated with a convalescent-phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of those treated 7 to 80 days (mean 20 days) after initial symptom resolution. Animal studies show convalescent plasma to be efficacious in Lassa fever as well, but only if it contains a high titer of neutralizing antibody (which is not automatically the case) and there is a close antigenic match between the infecting viruses of the donor and recipient. Convalescent plasma or blood has been given to numerous patients with Ebola hemorrhagic fever, but their efficacy is still unknown. Risk of concomitant transmission of other bloodborne pathogens and lack of an existing bank of immune plasma for VHF treatment are significant impediments to this approach in most countries. With the exception of for Argentine hemorrhagic fever, this therapy should be reserved for severe and refractory cases when ribavirin is not an option. Numerous mono- and polyclonal antibody preparations show promise in VHF animal models.

Coagulation modulators

A growing body of literature suggests that disturbances in the procoagulant–anticoagulant balance play an important role in the mediation of septic shock. Coagulation-modifying drugs that have been explored anecdotally in humans or in animal models of sepsis and/or VHF, with varying degrees of efficacy, included rNAPc2 (a potent experimental recombinant inhibitor of the tissue factor/factor VIIa coagulation pathway), recombinant factor VIIa itself (paradoxically, since it would have the opposite effect of rNAPc2), heparin sulfate, and antithrombin III. Lower mortality was recently noted in heparin-treated patients with severe sepsis in a phase III clinical trial. Nevertheless, use of coagulation modulators for VHF should still be considered experimental. Despite early promise, recombinant activated protein C is no longer recommended for septic shock or VHF.

Immune modulators

Trials of various immune modulators in septic shock or VHF, including ibuprofen, corticosteroids, anti-tumor necrosis factor-α (TNF-α), nitric oxide inhibitors, statins (HMG-CoA reductase inhibitors), and interleukins, have not shown conclusive benefit. Ribavirin combined with interferon (IFN) alfacon-1, a consensus IFN, diminished mortality in a hamster arenavirus model. Although approved for clinical use in humans, IFN alfacon-1 has not been tested in human VHF. In a small study, recombinant interleukin-2 reduced renal insufficiency in HFRS, but confirmation is needed before this can be considered the standard of care. There has been renewed interest in the use of corticosteroids for possible adrenal insufficiency in septic shock. Interestingly, viral infection of the adrenal cortex and adrenal gland necrosis have been reported in various VHFs. Results of a few clinical trials of corticosteroids in shock as well as in HFRS have been mixed. Furthermore, their use might exacerbate the immunosuppression common in some VHFs. Until more conclusive studies are conducted, corticosteroids should probably not be administered unless adrenal insufficiency is strongly suspected, the target blood pressure is not maintained despite adequate fluid repletion and vasopressors, or if cerebral edema is suspected. If necessary, a dose of 200 mg intravenous hydrocortisone per day in adults should be used, divided into two to

four daily doses or administer by continuous infusion.

Antibiotics and secondary infection

Patients should be immediately covered with appropriate antibacterial and/or antiparasitic therapy, with specific consideration of malaria and rickettsial disease, until VHF can be confirmed (Table 194.3). These drugs should then be stopped unless there is evidence of coinfection. Secondary bacterial infection should be suspected when patients have persistent or new fever after about 2 weeks of illness, when most VHFs have either resulted in death or are resolving.

Pain control, gastrointestinal stress ulcer prophylaxis, and management of seizures and other central nervous system manifestations

Oral or parenteral acetaminophen, tramadol, opiates, or other analgesics should be used as needed for pain control, adjusting as necessary for hepatic insufficiency. Avoid salicylates and nonsteroidal anti-inflammatory drugs because of the risk of bleeding. Prophylactic therapy for gastrointestinal stress ulcers with proton pump inhibitors or histamine-2 receptor antagonists is recommended. Antiemetics, such as the phenothiazines, are frequently warranted. Seizures can usually be managed with standard use of benzodiazepines, phenytoins, or levetiracetam, with careful attention to possible respiratory depression and hypotension. These drugs should not be given prophylactically.

Clinical laboratory testing

A broad range of clinical laboratory parameters should be monitored in patients with VHF (Table 194.4). Laboratory tests for DIC should be performed. Third-spacing, vomiting, diarrhea, decreased fluid intake, and the administration of intravenous fluids may result in significant electrolyte imbalance, especially hypokalemia, so regular potassium supplementation may be needed, keeping a close eye on renal function, which is often compromised in late disease. Although hyperglycemia has not been reported frequently in VHF, glucose should be monitored and levels kept <180 mg/dL via the use of intravenous insulin.

Nutrition

Gut feeding is preferable to parenteral alimentation when possible. Nasogastric tubes may be theoretically indicated for patients unable to eat, but there is little practical experience with their use in the VHFs. Exacerbation of gastrointestinal bleeding and heightened risk of transmission to healthcare workers during tube placement are concerns.

Management of pregnancy

Uterine evacuation in pregnant patients appears to lower maternal mortality and should be considered given the extremely high maternal and fetal mortality associated with VHF. However, this procedure must be performed with extreme caution, since it can be considered high risk with regard to nosocomial transmission. Although technically contraindicated in pregnancy (US Food and Drug Administration [FDA] Category X), ribavirin should nevertheless be considered, in consultation with the patient, as a lifesaving measure for the mother in VHFs for which the drug is efficacious (Table 194.2).

CONVALESCENCE AND SEQUELAE

Since patient clinical status and infectivity generally correlate with the level of viremia, patients who have recovered from their acute illness can safely be assumed to have cleared their viremia and discharged without concern of subsequent transmission at home. RT-PCR testing of blood and other body fluids has sometimes revealed residual nucleic acids, but the significance of this is unclear without cell culture confirming the presence of infectious virus. Sexual abstinence or condom use is recommended for 3 months because of the delayed virus clearance in the urine and semen, as well as simple precautions to avoid contact with excretions, including separate toilet facilities and regular hand washing, although transmission through toilet facilities has not been noted. Breastfeeding should be avoided unless there is no other way to support the baby.

Survivors usually suffer no obvious long-term sequelae, with the exceptions of deafness in Lassa fever and optic retinopathy with vision loss in Rift Valley fever, both of which appear during early convalescence and may persist for life to varying degrees. Nevertheless, convalescence may be prolonged, with persistent myalgia, arthralgia, anorexia, weight loss, alopecia, pancreatitis, uveitis, and orchitis up to a year after

infection. The psychological effects may also be significant, with some patients experiencing irritability, depression, post-traumatic stress disorder, or social stigmatization. Clinical management during convalescence is supportive.

INFECTION CONTROL

Patient isolation, personal protective equipment, and nursing precautions

Although normal barrier nursing and precautions to prevent parenteral and droplet exposure to blood and body fluids suffice in most instances, for added safety these should be upgraded to "VHF precautions" once the diagnosis is suspected, which includes patient isolation and the use of surgical masks, face shields, double gloves, gowns, head and shoe covers, and protective aprons. It is prudent to place the patient in a negative airflow room if available. Hermetically sealed isolation chambers are not required and may have profound negative psychological effects. Patient access should be limited to essential designated trained staff and family members. Use of sharps should be minimized. Small particle aerosol precautions, such as the use of high-efficiency particulate air filter masks, should be employed when performing procedures which may generate aerosols, including endotracheal intubation. The hospital laboratory should be alerted before sending specimens so that appropriate precautions can be implemented. Blood samples can be inactivated by the addition of detergents, such as Triton X-100, although their effect on the various laboratory parameters to be measured has not been firmly established. Use of point-of-care diagnostic assays at the bedside can further limit exposure to laboratory personnel. Disinfection of items coming into direct contact with the patient is advised, including chemical or heat inactivation of human waste.

Contact tracing

Given the generally low secondary attack rates, widespread contact tracing, laboratory testing, or postexposure prophylaxis are not indicated for casual contacts. Contacts should be defined as persons with unprotected direct contact with someone during the symptomatic phase of a human-to-human communicable VHF. Contacts should be monitored daily for the duration of the longest possible incubation period starting after their last contact (Table 194.2), checking and recording their temperature daily. It is usually recommended that exposed persons avoid intimate contact and sharing of utensils with household members for the duration of the incubation. Confinement of asymptomatic persons is not warranted. Persons who develop signs and symptoms suggestive of VHF should be immediately isolated and tested.

Postexposure prophylaxis

Postexposure prophylaxis should be considered in persons with distinct high-risk exposure defined as one of the following: (1) penetration of skin by a contaminated sharp instrument (e.g., needlestick injury), (2) exposure of mucous membranes or broken skin to blood or body secretions (e.g., blood splashing in the eyes or mouth), (3) participation in emergency procedures without appropriate personal protective equipment (e.g., resuscitation after cardiac arrest, intubation, or suctioning), and (4) prolonged (i.e., hours) and continuous contact in an enclosed space without appropriate personal protective equipment (e.g., a healthcare worker accompanying a patient during medical evacuation in a small airplane). Most infections come from contact with severely ill patients late in the course of illness.

Postexposure prophylaxis with oral ribavirin has been recommended for Lassa fever and other arenavirus infections and Crimean-Congo HF, although no systematically collected data on its efficacy are available. Because of the high first-pass metabolism of oral ribavirin, relatively high doses are needed to provide serum levels in the range of the minimum inhibitory concentration of most hemorrhagic fever viruses (Table 194.5). Persons taking prophylaxis who develop manifestations of VHF should also be immediately laboratory tested and converted to intravenous ribavirin unless the syndrome can be readily excluded. Convalescent plasma is also routinely given as postexposure prophylaxis for Argentine hemorrhagic fever. Numerous experimental approaches have shown efficacy as postexposure prophylaxis in VHF animal models but are not yet approved for use in humans.

Vaccines

The 17D live attenuated yellow fever vaccine has an excellent protection and safety profile, despite recent recognition of rare serious adverse events

Table 194.5. Ribavirin therapy for viral hemorrhagic fever

Indication	Route	Dose[a]	Interval
Treatment	IV[b]	30 mg/kg (maximum 2 g)[c]	Loading dose, followed by:
	IV[b]	15 mg/kg (maximum 1 g)[c]	Every 6 h for 4 days, followed by:
	IV[b]	7.5 mg/kg (maximum 500 mg)[c]	Every 8 h for 6 days
Prophylaxis	PO	35 mg/kg (maximum 2.5 g)[c]	Loading dose, followed by:
	PO	15 mg/kg (maximum 1 g)[c]	Every 8 h for 10 days

Abbreviations: IV = intravenous; PO = oral administration.

[a] Pharmacokinetic and sensitivity testing for ribavirin has not been extensively performed for each VHF. The intravenous dose used is derived from that found efficacious in Lassa fever. Oral ribavirin has also been reported to be efficacious in many VHFs, especially for Crimean-Congo HF, but few controlled data are available. IV administration is strongly suggested whenever possible.

[b] The drug should be diluted in 150 mL of 0.9% saline and infused slowly.

[c] Reduce the dose in persons know to have significant renal insufficiency (creatinine clearance of less than 50 mL/min).

in elderly persons. Confirmed previous vaccination should essentially rule out yellow fever. Candid 1, a highly efficacious live attenuated vaccine for Argentine hemorrhagic fever (only licensed in Argentina) may also be effective in Bolivian hemorrhagic fever but does not protect against other arenaviruses. Vaccines for HFRS, Rift Valley fever, and Kyasanur Forest disease exist but most are not widely tested, approved, or available. A number of experimental vaccines are efficacious in animal models of VHF. Clinical trials of various Ebola vaccines are underway.

195. Intestinal roundworms

Kathryn N. Suh and Jay S. Keystone

Nematodes (roundworms) are the most common parasites infecting humans worldwide. Of almost half a million species of roundworms, approximately 60 are known to be pathogenic to humans. Among the most prevalent human infections are those due to the intestinal (lumen-dwelling) nematodes. *Ascaris lumbricoides* and *Trichuris trichiura* each infect over 1 billion people worldwide; hookworms (*Ancylostoma duodenale* and *Necator americanus*) infect almost the same number. Other important nematodes of humans include *Strongyloides stercoralis* and *Enterobius vermicularis*. Coinfection, in particular with *A. lumbricoides* and *T. trichiura*, is common.

Ascaris lumbricoides, hookworm, and *T. trichiura*, collectively referred to as geohelminths (or soil-transmitted helminths), share the requirement for eggs or larvae to mature in soil in order to be infective to humans. Due to this obligate soil stage of maturation, these parasites cannot be transmitted from person to person. In contrast, *S. stercoralis* is able to complete its entire life cycle within the human host, and like *E. vermicularis*, both person-to-person transmission and autoinfection can occur.

The majority of geohelminthic infections are asymptomatic and associated with low worm burdens, whereas the minority (15%–35%) of infected individuals harbor the majority of the worm burden and suffer from more intense symptoms. Geohelminthic infections are important contributors to growth retardation and cognitive delay in children, but conclusively proving the benefit of large-scale anthelminthic therapy in endemic areas is challenging for a number of reasons. Geohelminths are unaffected by host immune responses, leading to chronic infection if untreated, although the natural history of such infections (excluding hookworm) is usually one of decreasing worm burden over time; even with treatment, however, reinfection is common.

The prevalence and intensity of helminthic infections, and in particular geohelminthic infections, are related to poverty, educational and agricultural standards, population density, and sanitary (public health) conditions, all of which have a far greater impact on the burden of disease than do ecologic factors.

ASCARIASIS

Ascariasis is among the earliest recorded and most prevalent helminthic infections of humans. King Richard III's body, recently discovered in the United Kingdom, contained *Ascaris* eggs. Disease is caused by *A. lumbricoides*; infection due to the closely related porcine ascarid *Ascaris suum* has been reported following accidental ingestion of ova. Ascariasis is widely distributed throughout the world, with the highest prevalence in Asia and in young children. Complications of infection are generally related to a high worm burden, and thus only a minority of infected individuals is at risk of serious morbidity. The prevalence of ascariasis is attributable in part to the prodigious output of eggs by each adult female and the ability of these eggs to survive in a diverse range of environmental conditions.

The life cycle of *Ascaris* is shown in Figure 195.1. Fertilized eggs are excreted in stool, embryonate, and become infective after a period of weeks to months in soil, depending on environmental conditions. One to two days after infective eggs are ingested, larvae are released in the small bowel, penetrate the intestinal wall, travel to the pulmonary circulation, and enter the lungs, where they ascend the trachea and are swallowed. Approximately 10 weeks after ingestion of eggs, larvae mature into adults in the small intestine, where they live for up to 18 months. Egg production occurs 3 to 4 months after initial ingestion; females can produce more than 200 000 eggs per day.

Most *Ascaris* infections are asymptomatic. Adult worms may be seen in emesis or stool and are occasionally coughed up or extruded

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

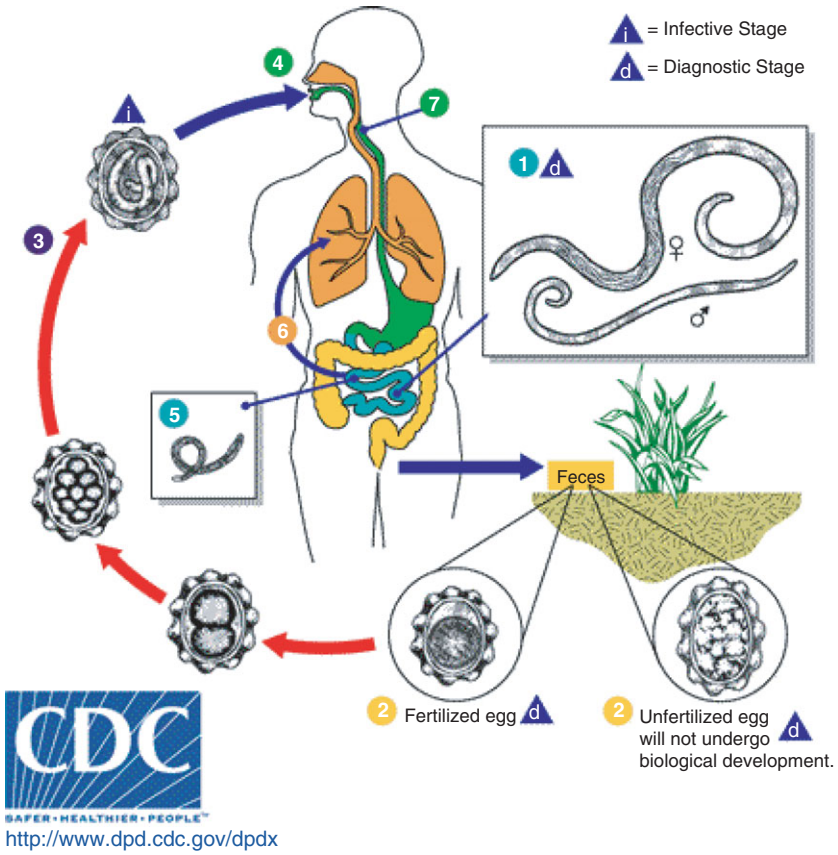

Figure 195.1 Life cycle of *Ascaris lumbricoides*. Adult worms (1) live in the lumen of the small intestine. A female may produce approximately 200,000 eggs per day, which are passed with the feces (2). Unfertilized eggs may be ingested but are not infective. Fertile eggs embryonate and become infective after 18 days to several weeks (3), depending on the environmental conditions (optimum: moist, warm, shaded soil). After infective eggs are swallowed (4), the larvae hatch (5), invade the intestinal mucosa, and are carried via the portal, then systemic circulation to the lungs (6). The larvae mature further in the lungs (10 to 14 days), penetrate the alveolar walls, ascend the bronchial tree to the throat, and are swallowed (7). Upon reaching the small intestine, they develop into adult worms (1). Between 2 and 3 months are required from ingestion of the infective eggs to oviposition by the adult female. Adult worms can live 1 to 2 years.

through the nose. Loeffler's syndrome, characterized by migratory pulmonary infiltrates and peripheral eosinophilia, results from larval migration through the pulmonary parenchyma and may develop within 2 weeks of ingestion. Clinical manifestations include fever, dyspnea, wheezing, and dry cough. Gastrointestinal complications are generally due to a heavy adult worm burden (e.g., intestinal obstruction from worm masses) or to migration of a single adult worm into the bile or pancreatic duct or the appendix. Complications from worms in other organs are rare.

Ascariasis is diagnosed by the demonstration of ova, larvae, or adult worms. Eggs are readily demonstrated in stool. Barium studies occasionally demonstrate adult worms, either by outlining them with barium or by visualizing ingested barium within the gut of the worm. Eosinophilia is not a feature of adult ascariasis but is a common finding during the migration phase.

Because of the potential for worm migration, all infections, whether symptomatic or not, should be treated. When mixed helminthic infections are being treated, *Ascaris* should always be treated first, because medications may stimulate

Table 195.1 Treatment of intestinal roundworm infections

Disease	Drug	Adult and pediatric dose
Ascariasis	Albendazole	400 mg 1×
	or	
	Mebendazole	500 mg 1× or 100 mg BID × 3 d
	or	
	Pyrantel pamoate	11 mg/kg (max 1 g) daily × 3 d
	or	
	Ivermectin	150–200 μg/kg 1×
Trichuriasis	Albendazole	400 mg daily × 3 d
	or	
	Mebendazole	100 mg BID × 3 d
	or	
	Ivermectin	200 μg/kg daily × 3 d

	or	
	Pyrantel pamoate	11 mg/kg (max 1 g) 1×
	or	
	Albendazole	400 mg × 3 d
	or	
	Mebendazole	100 mg BID × 3 d

[a] Regardless of the agent used, therapy must be repeated 2 to 4 weeks after the first course.

worms to migrate. Mebendazole or albendazole is appropriate first-line therapy (Table 195.1). Single-dose therapy with either achieves acceptable cure rates.

TRICHURIASIS

Like ascariasis, trichuriasis is a widely distributed disease. Humans are the only hosts of *T. trichiura* (whipworm, so named for the characteristic morphology of adult worms). It is most common in tropical climates, with the highest prevalence in children. Human disease may rarely be caused by related species of porcine (*Trichuris suis*) and canine (*Trichuris vulpis*) whipworm.

Eggs passed in stool embryonate after 2 to 4 weeks of maturation in soil. There is no tissue (pulmonary) phase; eggs are deposited directly in the cecum, where larvae hatch and mature into adults over several days. Adult worms survive for up to 8 years in the cecum, where they remain attached to the intestinal mucosa. Egg production begins 2 to 3 months after initial infection, with females releasing up to 20 000 eggs per day.

Most infected individuals are asymptomatic. Moderate worm burdens may cause nonspecific gastrointestinal symptoms, including abdominal pain or distension or diarrhea. Heavy worm burdens more often affect children and may lead to profuse bloody diarrhea or rectal prolapse, the hallmark of trichuriasis in endemic areas. Iron deficiency anemia may also be present, but eosinophilia is uncommon.

The diagnosis of *T. trichiura* infection rests on demonstration of eggs or adult worms. Endoscopy may reveal colitis and the presence of visible worms hanging within the intestinal lumen. Treatment with a 3-day course of mebendazole or albendazole is recommended (Table 195.1), as single-dose therapy leads to suboptimal cure rates.

HOOKWORM INFECTION

Hookworm infection affects approximately 740 million individuals, with most cases in Asia and sub-Saharan Africa. Disease due to *Necator americanus* is most common and is found predominantly in tropical climates, whereas *Ancylostoma duodenale* infection is more geographically restricted, occurring in northern India; North Africa; the Middle East; and parts of China, Southeast Asia, and South America. Prevalence increases throughout early childhood and then plateaus in early adulthood, with worm burden remaining essentially constant (or declining modestly) throughout the life of the infected host. Other hookworm species, including *Ancylostoma ceylanicum* and *Ancylostoma caninum*, rarely cause enteritis, whereas *Ancylostoma braziliense* infection typically causes cutaneous larva migrans.

The life cycle of hookworm resembles that of *Ascaris*. Eggs are excreted in stool and hatch

in soil, and within 7 days larvae become infective. Following penetration of intact skin, larvae migrate through lymphatics to enter the bloodstream and travel to the lungs, ascend the trachea, and are swallowed. *Ancylostoma duodenale* larvae may also cause infection by the oral route. Within the small intestine, larvae mature into adults and attach themselves to the intestinal mucosa. *Ancylostoma duodenale* adults survive for up to 1 year, and *N. americanus* for up to 9 years. Egg production begins 1.5 to 2 months after infection. Females release 5 to 30 000 eggs per day, depending on the infecting species.

An intensely pruritic erythematous maculopapular eruption, "ground itch," may develop at entry points of filariform larvae. Dermatitis is more likely with repeated exposure and can be complicated by secondary infection. Loeffler's syndrome may occur 10 to 14 days after infection, and may be accompanied by an urticarial eruption. Nausea, epigastic pain, or abdominal tenderness may be present early in the course of disease and with heavy worm burdens. Infection by the oral route may lead to pharyngeal irritation, hoarseness, cough, and nausea (Wakana disease). The hallmark of hookworm infection is chronic iron deficiency anemia, which results from local blood loss at the site of attachment of the adult worms as well as from their ingestion of blood. The occurrence and severity of anemia depend on the infecting species of hookworm (*A. duodenale* causes more blood loss than *N. americanus*), the intensity of infection, the iron reserves of the host, and the availability of iron in the diet; therefore, hookworm anemia is mostly seen in developing countries, where a hemoglobin of 3 to 8 g/dL is not unusual. Complications of severe anemia, including weakness, fatigue, and high-output cardiac failure, are common. Infection and resultant anemia during pregnancy are associated with low birth weight and increased neonatal mortality.

In addition to laboratory findings of iron deficiency anemia, eosinophilia is common. Hypoalbuminemia may result from protein-losing enteropathy. The diagnosis is made by identification of hookworm ova in the stool; fecal concentration techniques are not usually required. Occasionally, rhabditiform larvae may be present in stool and must be differentiated morphologically from those of *Strongyloides*. Mebendazole and albendazole are drugs of choice for treatment (Table 195.1). Vaccine development is currently in progress.

STRONGYLOIDIASIS

Human strongyloidiasis is caused primarily by *S. stercoralis*, which is endemic to Africa, Asia, Southeast Asia, and Central and South America, where 20% or more of the population may be infected. Disease is also found in the Caribbean and to a much lesser extent in Europe, Japan, Australia, and parts of the southern United States. Infection caused by *Strongyloides fuelleborni*, found sporadically in Africa and Papua New Guinea, is relatively rare. Strongyloidiasis affects between 30 and 100 million individuals worldwide.

The life cycle of *S. stercoralis* is complex (Figure 195.2). Rhabditiform larvae released in the stool of infected hosts mature into infective (filariform) stages in soil. Infection usually results from the penetration of intact skin by filariform larvae. These travel via the circulatory system to the lungs where they penetrate the alveoli, ascend the trachea, are swallowed, and then mature into adult worms in the small intestine. Although sexual reproduction does take place within the intestine, adult females are also parthenogenetic (capable of reproduction without males). Eggs are deposited in the intestinal mucosa, hatch, and release rhabditiform larvae, which are excreted in the stool to begin another cycle. Rhabditiform larvae in the bowel may also transform directly into filariform larvae that enter the circulation and begin another cycle of infection (autoinfection) or, in the appropriate clinical setting (i.e., immunosuppression), may lead to disseminated disease (hyperinfection syndrome). Rhabditiform larvae have the capacity to develop into adults in soil where they reproduce sexually (heterogonic development) and give rise to infective filariform larvae (Figure 195.2).

Most infected persons have low worm burdens and are persistently infected for life, often with minimal or no symptoms. If symptoms are present they are generally intermittent, with long asymptomatic periods between episodes. Acute infection may be apparent with very rapid (1–2 cm/hour) migratory serpiginous skin lesions (larva currens) or urticaria at the sites of larval penetration; cutaneous larva migrans from dog or cat hookworms may produce a similar picture, but with much slower migration in skin (1–2 cm/day). Larva currens in the perianal area is pathognomonic of chronic strongyloidiasis. Urticarial rashes may occur over many years

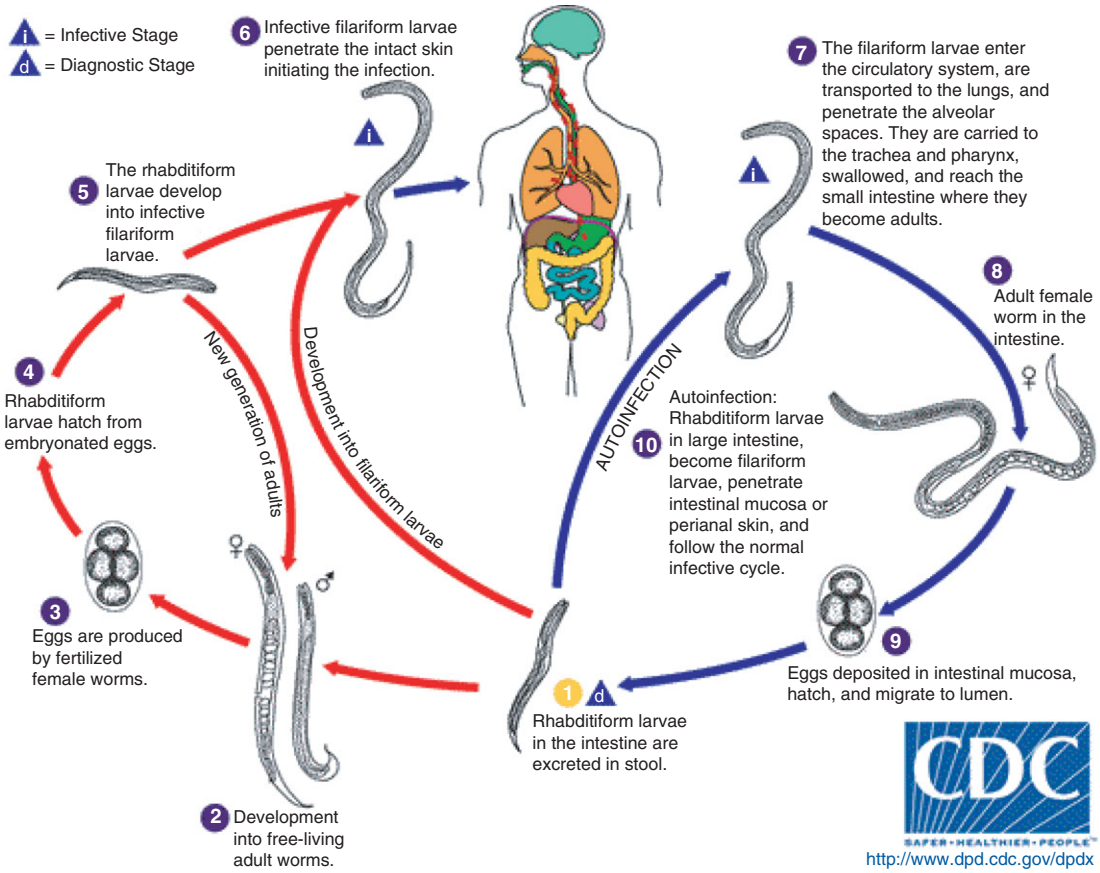

Figure 195.2 Life cycle of *Strongyloides stercoralis*. The *Strongyloides* life cycle is more complex than that of most nematodes with its alternation between free-living and parasitic cycles, and its potential for autoinfection and multiplication within the host. Two types of cycles exist:

Free-living cycle: The rhabditiform larvae passed in the stool (1) (see "Parasitic cycle" below) can either molt twice and become infective filariform larvae (direct development) (6) or molt four times and become free-living adult males and females (2) that mate and produce eggs (3) from which rhabditiform larvae hatch (4). The latter in turn can either develop (5) into a new generation of free-living adults (as represented in (2)), or into infective filariform larvae (6). The filariform larvae penetrate the human host skin to initiate the parasitic cycle (see below) (6).

Parasitic cycle: Filariform larvae in contaminated soil penetrate the human skin (6), and are transported to the lungs where they penetrate the alveolar spaces; they are carried through the bronchial tree to the pharynx, are swallowed and then reach the small intestine (7). In the small intestine they molt twice and become adult female worms (8). The females live threaded in the epithelium of the small intestine and by parthenogenesis produce eggs (9), which yield rhabditiform larvae. The rhabditiform larvae can either be passed in the stool (1) (see "Free-living cycle" above), or can cause autoinfection (10). In autoinfection, the rhabditiform larvae become infective filariform larvae, which can penetrate either the intestinal mucosa (internal autoinfection) or the skin of the perianal area (external autoinfection); in either case, the filariform larvae may follow the previously described route, being carried successively to the lungs, the bronchial tree, the pharynx, and the small intestine where they mature into adults; or they may disseminate widely in the body. To date, occurrence of autoinfection in humans with helminthic infections is recognized only in *Strongyloides stercoralis* and *Capillaria philippinensis* infections. In the case of *Strongyloides*, autoinfection may explain the possibility of persistent infections for many years in persons who have not been in an endemic area and of hyperinfections in immunodepressed individuals.

Source: Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention, Atlanta, GA. http://www.dpd.cdc.gov/dpdx/HTML/Strongyloidiasis.htm, accessed 13 September 2013.

during chronic infection. Pulmonary manifestations of disease are unusual due to the small numbers of larvae passing through the lungs, except at the onset of a heavy infection or, more commonly, when hyperinfection syndrome is present (see below). Epigastric pain mimicking peptic ulcer disease and persistent abdominal pain, diarrhea, and anorexia are common manifestations of symptomatic chronic infection. Abdominal bloating, distension, and intestinal malabsorption can also occur.

Hyperinfection syndrome most often occurs in the presence of impaired cellular immunity, typically due to the use of systemic steroids. Other chemotherapeutic agents, hematologic malignancies (notably lymphoma), organ transplants, malnutrition, chronic alcoholism, and coinfection with human T-lymphotropic virus 1 (HTLV-1) are also predisposing factors. Interestingly, human immunodeficiency virus infection is not associated with an increased risk of disseminated disease. Insidious gastrointestinal symptoms may be present. Pulmonary disease is the most common extraintestinal manifestation of hyperinfection syndrome and is characterized by diffuse pulmonary infiltrates with dyspnea, cough, wheezing, or hemoptysis. In uncontrolled hyperinfection, filariform larvae also penetrate organs not normally involved in the life cycle, including the urinary tract, liver, and brain. Gram-negative and occasionally gram-positive bacterial infections, including bacteremia, peritonitis, meningitis, and sepsis, may result from the concurrent migration of bacteria and larvae across the bowel wall. The triad of hemorrhagic pneumonitis, enteritis, and gram-negative bacteremia in an immigrant who is immunocompromised should lead to consideration of disseminated strongyloidiasis. The mortality rate for disseminated disease is approximately 50%.

The diagnosis of chronic strongyloidiasis is difficult due to the nonspecific symptoms of the disease and the minimal, irregular larval output in stool. Demonstration of larvae in clinical specimens (e.g., stool, bronchial washings in disseminated infection) is diagnostic but insensitive. In gastrointestinal infection, a single stool specimen may fail to detect larvae in up to 70% of cases, although sensitivity approaches 100% with seven consecutive stool samples. Specialized laboratory techniques (e.g., Baermann concentration; Harada–Mori filter paper test) and duodenal aspirates are more sensitive than single stool examinations but are impractical to perform. The agar plate method, in which stool is plated on solid medium and incubated for up to 72 hours, is highly sensitive (96%) but has a slow turnaround time. Agar plate specimens containing *S. stercoralis* larvae will, after incubation, reveal linear tracks formed by bacteria that have been carried by motile larvae. Peripheral eosinophilia is present in up to 80% of patients with intestinal disease and can be a clue to diagnosis, but it is rarely a feature of disseminated infection (although pulmonary eosinophilia may be noted in the latter). *Strongyloides* serology has a reported sensitivity of 88% to 95% and specificity of 39% to 99%. Its use is limited by cross-reactivity with other helminthic infections (in particular filariasis, ascariasis, and acute schistosomiasis), and the inability of a positive result to distinguish between treated or ongoing infection, because antibodies may persist for years following effective treatment. However, antibody levels drop significantly over the first year following successful therapy, allowing serology to be used as a test of cure. Polymerase chain reaction and luciferase immunoprecipitation assays are promising new approaches to diagnosis but are currently available only in research settings.

Treatment of strongyloidiasis in asymptomatic individuals is often successful, whereas those with disseminated disease may require prolonged or repeated courses of therapy. Currently, ivermectin is considered the treatment of choice. If possible, immunosuppressant therapy should be discontinued in those with hyperinfection. Prevention of disease by screening and/or presumptive treatment of at-risk individuals is desirable. Recommended regimens are summarized in Table 195.1.

ENTEROBIASIS

In contrast to other gastrointestinal helminthic infections, *E. vermicularis* infection (pinworm, threadworm) does not respect socioeconomic boundaries. *E. vermicularis* is ubiquitous, found in both urban and rural settings worldwide. Enterobiasis is the most common helminthic infection in North America and is among the most prevalent throughout the world. Humans are the only hosts, with infection occurring most commonly in young children.

Eggs are ingested, either by the fecal–oral route or by exposure to contaminated fomites. There is no tissue phase of infection. Larvae hatch in the upper gastrointestinal tract and mature into adults. Adult worms mate in the small intestine before migrating to the appendix and cecum,

where they survive for up to 13 weeks. Gravid females migrate to the perianal area, where they release over 10 000 eggs daily, beginning 3 to 7 weeks after infection.

Symptoms are rarely serious, but may be problematic. Nocturnal pruritus ani is the most common symptom and can lead to insomnia and irritability. Local bacterial infection as a result of scratching can occur. Gastrointestinal and other attributable symptoms appear to be infrequent. Abdominal pain or diarrhea should prompt a search for *Dientamoeba fragilis*, because the coinfection rate with *E. vermicularis* may be as high as 50%; recent studies suggest that *D. fragilis* is transmitted in or on pinworm eggs. There is no evidence of an association between pinworm infection and behaviors such as tooth grinding, nail biting, or enuresis.

Eosinophilia is not a feature of enterobiasis. The diagnosis is established by identifying adult worms or eggs. The most reliable approach is the cellulose tape test using transparent adhesive tape to demonstrate eggs on perianal skin. A wooden tongue depressor draped with tape (sticky side out) is firmly pressed against the perianal skin immediately on waking in the morning, before defecation or bathing. The tape is removed, placed sticky side down on a slide, and examined under a microscope. Ninety percent of infections can be detected with three slides obtained on consecutive mornings, and seven tests detect 100% of infections. In contrast, routine stool examination for ova and parasites is positive in only 10% to 15% of infected persons. Treatment of a suspected infection "on spec" may be a more practical approach than using cellulose tape or pinworm paddles.

The treatment of enterobiasis is summarized in Table 195.1. In the absence of reinfection or autoinfection, a primary infection will clear without treatment in 30 to 45 days. Because intrafamilial transmission is common, treatment of the entire family is recommended. A second course of therapy administered 2 to 4 weeks after the first will treat possible autoinfection or reinfection because medications are relatively ineffective against developing larvae and newly ingested eggs. Specific personal hygiene measures such as good hand hygiene, daily bathing in the morning, the use of underwear and pyjamas for sleeping at night, daily change of underwear, and regular laundering of bedclothes are also important for eradication of infection. Recurring infections should be treated at least four times at 2-week intervals.

TRICHOSTRONGYLIASIS

Trichostrongylus species are parasites of herbivores such as sheep, cattle, and goats, primarily in the Middle East and Asia; humans are accidental hosts. Ova released in the feces of infected animals hatch in soil within 1 to 2 days, and pass through three free-living stages before becoming infective. Human infection typically results from ingestion of larvae in contaminated food or water, although larvae can also penetrate skin. There is no tissue phase, and adults reside embedded in the duodenal or upper jejunal mucosa. Little is known about the pathology of human trichostrongyliasis.

Most human infections are mild and asymptomatic, but diarrhea, flatulence, and epigastric pain may occur. Peripheral eosinophilia may be marked but is more commonly absent. Diagnosis depends on identification in stool of ova, which are often difficult to differentiate from hookworm ova. Treatment is outlined in Table 195.1.

ANISAKIASIS

Anisakiasis (anasakidosis; herring worm or codworm disease), caused by infection with the third-stage larvae of *Anisakis simplex* or *Pseudoterranova decipiens*, is most prevalent in Japan and less frequent in Hawaii and the coastal areas of North America and northern Europe. It is acquired by consumption of raw or inadequately cooked marine fish or squid, as found in sushi or ceviche, for example. The primary hosts of anisakids are sea mammals, including dolphins, porpoises, whales, seals, sea lions, and walruses. Eggs released in feces mature in seawater. Free-swimming second-stage larvae are ingested by small marine crustacea and develop into third-stage (infective) larvae in squid and predatory fish. Herring, salmon, mackerel, cod, and squid are important sources of infection for humans. Larvae ingested by consumption of raw or inadequately cooked fish invade the submucosa of the stomach or intestine but cannot mature into adult worms in the human host. The larvae cause local inflammation and hemorrhage that generally last about 10 days.

Anisakiasis is categorized into gastric, intestinal, or extraintestinal disease. The presentation varies depending on both geography and the infecting species. Gastric anisakiasis usually presents acutely after ingestion of infected food and presents with severe epigastric pain, nausea, and vomiting. Acute symptoms subside in a few days,

but intermittent nausea, vomiting, and vague abdominal pain may persist for weeks to months. Symptoms of intestinal anisakiasis develop 1 to 5 days after the infecting meal and are due to invasion of the distal ileum. Abdominal pain, nausea, vomiting, and mild leukocytosis occur. Extraintestinal complications include peritonitis and pleurisy caused by larval perforation of the intestinal wall. Hypersensitivity reactions, including anaphylaxis, have also been associated with anisakiasis.

With the appropriate history and presenting symptoms, the diagnosis of gastric anisakiasis can be most easily confirmed by endoscopy. An ulcerated lesion and the protruding larva may be visualized. Intestinal and extraintestinal anisakiasis are difficult to differentiate from other causes of acute abdomen, and patients often undergo laparotomy. Serologic diagnosis may be helpful but is not readily available. Peripheral eosinophilia is common. Treatment includes removal of the parasite and supportive care, although even untreated infection subsides in a few days. Anthelmintic therapy for human anisakiasis is not well established, although albendazole has been reported to be effective.

196. Tissue nematodes

Thomas A. Moore

Tissue-dwelling helminths include a large number of nematodes, cestodes, and trematodes that cause a wide variety of clinical manifestations. Immunoglobulin E (IgE) elevations tend to accompany eosinophilia due to helminth infections, but a normal level does not eliminate parasitic disease. The diagnostic considerations can be narrowed through an understanding of the various parasites, specifically the geographic distribution, the likelihood of exposure in endemic areas, incubation periods, and knowledge of the common manifestations of infection. Serologic tests are sometimes helpful, but panels of helminth serologic tests are most likely to be unrewarding if not confusing. Treatment strategies must be tailored to the individual parasitic disease.

TRICHINELLOSIS

Trichinellosis develops when raw or inadequately cooked meat containing the encysted larvae of *Trichinella* species is eaten. The larvae are released from the cysts by digestive enzymes in the stomach of the host, migrate to the small intestine villi where they penetrate the intestinal mucosa, and undergo four successive molts in about 24 hours to develop into male and female adult worms. After ~1 week, infective newborn larvae are released and invade striated muscle via the circulation, where they encyst within individual muscle fibers.

Trichinellosis has a worldwide distribution, occurring in temperate and tropical climates. It is considered an emerging zoonosis with increased rates of infection, attributed to changing human dietary habits and breakdown in some developing countries of veterinary management practices. In the United States, trichinellosis has historically been associated with eating *Trichinella*-infected pork from domesticated sources. Improved observance of standards and regulations in the US commercial pork industry has resulted in a steady reduction of *Trichinella* prevalence among swine. The number of reported cases related to eating nonpork products has remained constant, however, and exceeds the number of reported cases related to eating pork.

Among US travelers, most cases of trichinellosis have been associated with consumption of wild pigs, especially the bush pig and warthog. Meat from other sources can result in trichinellosis as well, and outbreaks of the disease have been associated with consumption of meat from bears, walruses, and horses. Most reported travel-related infections have been associated with visits to Mexico, Southeast Asia, and sub-Saharan Africa.

In the 5-year period from 2002 through 2007, 66 cases of trichinellosis were reported to the Centers for Disease Control and prevention (CDC). Of the 54 cases available for analysis, 27 cases (50%) were exclusively associated with eating wild game: bear (22), cougar (1), wild boar (2), deer (1), and walrus or seal (1). In comparison, only 8 cases (15%) were associated with eating commercial pork products, including 2 cases traced to a foreign source. The source for 17 cases (31%) was not known.

The severity of symptoms depends on the number of ingested larvae. Because most infections result from ingestion of a small number of larvae, most infected persons are asymptomatic. The adult worm in the small intestine may cause gastrointestinal symptoms within a week of infection. Symptoms include abdominal discomfort, vomiting, and diarrhea, which may evolve into fulminant enteritis in unusually heavy infections. However, most clinical manifestations are related to systemic invasion by larvae, and they usually begin in the second week after infection, peak over a week's time, then slowly subside. These symptoms include fever and myositis with pain, swelling, and weakness. Myositis usually begins in the extraocular muscles and progresses to involve the masseters, neck muscles, and limb flexors. Other symptoms include headache,

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

cough, and dysphagia. Occasionally subconjunctival or subungual splinter hemorrhages develop. A petechial or macular rash is sometimes seen. In fulminant infection myocarditis, pneumonia, and encephalitis may be fatal.

Fever and eosinophilia associated with periorbital edema and myositis are the cardinal features of trichinellosis. Eosinophilia begins about 10 days after infection and may be quite high. The erythrocyte sedimentation rate is usually normal. Elevated creatine phosphokinase and lactate dehydrogenase levels reflect extensive muscle involvement.

Serologic testing is available from the CDC, but antibodies are not detectable until at least 3 weeks after infection. Although muscle biopsy may confirm the diagnosis, it is usually unnecessary.

Therapy

The goal of treatment in early infection is to limit muscle invasion by larvae; when this has already occurred, the goal is to reduce muscle damage, which is responsible for the major clinical manifestations. Specific treatment with mebendazole, 400 mg twice daily for 10 days, or albendazole, 400 mg twice daily for 10 days, has been shown to be effective for intestinal and muscle stages. Thiabendazole is no longer used because of its side effects. The mainstays of symptomatic treatment remain bed rest and salicylates. Glucocorticoids (prednisone, 60 mg/day for 7 days with a subsequent taper over 7 days) are effective for severe symptoms not relieved by salicylates. Persons who are known to have recently eaten trichinous meat should be given a 7-day course of albendazole, 400 mg orally twice daily, or thiabendazole, 25 mg/kg/day (max, 3 g/day), in order to eliminate the intestinal infection.

FILARIASIS

Of the eight filarial species capable of infecting humans, the four that cause the most disease worldwide are *Brugia malayi*, *Wuchereria bancrofti*, *Onchocerca volvulus*, and *Loa loa*. Because only a small proportion of insect bites is infective, the disease generally occurs only after long exposure in an endemic area. The clinical manifestations of filariasis depend in part on the immune response of the host. The response to the parasite in endemic populations is dampened, and a large parasite burden is common. In contrast, individuals who have grown up outside of endemic regions and become infected manifest prominent signs and symptoms and usually have a low parasite burden.

Lymphatic filariasis

Lymphatic filariasis is caused by infection with one of the lymph-dwelling filariae, *W. bancrofti, B. malayi*, or *Brugia timori.* An infected mosquito deposits larvae in subcutaneous tissue. Over time, the larvae mature into adult worms. These threadlike adults reside in afferent lymphatic channels or sinuses of lymph nodes. All lymph-dwelling filariae contain *Wolbachia*, an intracellular bacterial endosymbiont that is essential for their growth, development, fertility, and survival.

W. bancrofti, found in tropical and subtropical regions throughout the world, is the most widely distributed human filaria. In most of the world the parasite is nocturnally periodic, with the microfilariae scarce in peripheral blood during the day but increased at night. In the Pacific Islands, however, the microfilariae are subperiodic; microfilaremia is seen throughout the day, reaching maximal levels in the afternoon. Brugian filariasis occurs throughout Asia and the Far East, including India and the Philippines. This form of filariasis is nocturnally periodic, except in forested areas, where it is subperiodic.

Among endemic populations, the common manifestations of lymphatic filariasis include asymptomatic microfilaremia, filarial fevers, and lymphatic obstruction. Most infected individuals are clinically well and have an asymptomatic condition associated with microfilaremia. More than half of these patients have hematuria, proteinuria, or both. Filarial fevers are acute episodes of fever and chills accompanied by lymphangitis and lymphadenitis with transient lymphedema. The episodes abate after a week to 10 days but can recur. Importantly, the lymphangitis develops in a descending fashion, opposite the direction seen in cellulitis. Regional lymphadenopathy is often present and thrombophlebitis may develop. Both upper and lower extremities may be involved but genital involvement, which may manifest as epididymitis, funiculitis, and scrotal pain and tenderness, is found exclusively with *W. bancrofti*.

Damage to the lymphatics, with resultant obstruction, manifests early as pitting edema. The edema eventually causes characteristic features of elephantiasis, with thickening of subcutaneous tissues, hyperkeratosis, and fissuring of skin. Lymphedema renders patients susceptible to recurrent bacterial and fungal infections.

Figure 196.1 Massive scrotal swelling in lymphatic filariasis.

Hydrocele formation is the most common manifestation of lymphatic filariasis and scrotal lymphedema may develop (Figure 196.1). If retroperitoneal lymphatics are obstructed, chyluria develops.

Persons new to endemic areas who acquire lymphatic filariasis usually develop acute lymphatic inflammation with lymphangitis, lymphadenitis, and, in the case of *W. bancrofti*, genital pain, but they may also develop allergic phenomena such as hives, urticaria, and eosinophilia.

Lymphatic filariasis is suspected from epidemiologic history, physical findings, and laboratory tests. However, a definitive diagnosis can be made only by detecting the parasite. Adult worms in lymphatics are generally inaccessible and excisional biopsies are unhelpful; however, ultrasonographic examination of the scrotum or breast in females using a high-frequency (7.5–10 MHz) transducer with Doppler may demonstrate motile adult worms within dilated lymphatics (the so-called "filarial dance sign"). Additional supportive data can be obtained with the use of lymphoscintigraphy, which (in early infections) will demonstrate a paradoxically brisk lymphatic flow on the affected side.

Microfilariae can be detected in blood and occasionally in other body fluids. Detection of microfilariae in the blood is most efficiently performed by filtering 1 mL or more of blood through a polycarbonate filter with 3-μm pores or examining the sediment from a Knott's prep (1 mL of blood with 10 mL of 2% formalin). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region in question. Filtration of blood for nocturnally periodic microfilariae should be performed between 10 p.m. and 4 a.m. A 10- to 14-day period is required for microfilarial periodicity to adjust to local time zones.

Assays that detect circulating antigens of *W. bancrofti* (but not *Brugia* spp.) are commercially available and permit the diagnosis of filariasis in patients without microfilaremia. Polymerase chain reaction (PCR)-based assays that detect DNA of *W. bancrofti* and *B. malayi* have been developed but are not commercially available.

Data supporting filarial infection include eosinophilia, elevated serum IgE levels, and antifilarial antibodies in the serum. Serologic studies have greater diagnostic value in persons new to endemic areas. A negative or low antibody level effectively rules out active infection in this population. However, interpretation of serologic findings may be problematic because of cross-reactivity between filarial antigens and antigens of other helminths, such as *Strongyloides stercoralis*. In addition, residents of endemic areas may develop antibodies to filarial antigens through the bites of infected mosquitoes without developing patent infection.

THERAPY

The mainstay of treatment remains diethylcarbamazine (DEC) 6 to 8 mg/kg/day in single or divided doses for 12 days. DEC, an orphan drug, can be obtained from the CDC drug service (telephone 404–639–3670). Although extended treatment is usually necessary to kill the adults, a single dose rapidly kills microfilariae. The severity of adverse reactions correlates with the pretreatment level of microfilaremia, but the etiology is unclear and may represent either an acute hypersensitivity reaction to massive antigen release or an inflammatory reaction induced by the release of *Wolbachia*. Usually the reactions, which include fevers, headache, lethargy, arthralgias, and myalgias, can be easily managed with antipyretics and analgesics. Initiating treatment

with a small dose of DEC (e.g., a single 50 mg tablet) and premedicating the patient with corticosteroids, 0.5 to 1 mg/kg/day, minimizes side effects.

Albendazole (400 mg PO BID × 21 days) is also effective against adult worms. Doxycycline (100 mg PO BID × 4–8 weeks) targets the intracellular *Wolbachia* and also demonstrates effective macrofilaricidal activity. Additional treatment regimens shown to be effective include DEC and albendazole for 7 days or DEC and doxycycline for 21 days.

A note of caution: the geographic distribution of loiasis overlaps with lymphatic filariasis and coinfection occurs. Since treatment of loiasis with both DEC and ivermectin can result in severe adverse effects (see below), it is imperative to exclude the possibility of coinfection with loiasis prior to treating patients with lymphatic filariasis.

Because adult worms may survive the initial treatment, symptoms can recur within a few months after therapy, and retreatment is recommended for such patients. Some individuals have suggested treating such patients with DEC at the standard dose of 6 to 8 mg/kg/day for 1 week each month for 6 to 12 months. Combination therapy with DEC and either albendazole or ivermectin (sometimes preceded by doxycycline) has demonstrated efficacy for mass chemotherapy of filariasis.

The optimal treatment of acute lymphatic inflammation is unknown, and these attacks usually resolve in 5 to 7 days without therapy. Treatment of chronic lymphatic obstruction is problematic. If the infection is recognized early, some signs of lymphatic obstruction can be reversed. In severely damaged lymphatics, however, supportive measures are used, including elevation of the infected limb, elastic stockings, and foot care with antifungal ointments and antibacterial antiseptics. Prophylactic antibiotics may prevent recurrent bacteremia and cellulitis. Hydroceles can be managed surgically, and surgical decompression with a nodovenous shunt may provide relief for severely affected limbs. No treatment has proved satisfactory for chyluria. DEC is useful for prophylaxis, but the optimal dose and frequency have not been established.

Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome caused by immunologic hyperresponsiveness to *W. bancrofti* or *B. malayi*. The syndrome affects men four times as commonly as women, often in the third decade of life. Most cases have been reported from Pakistan, India, Sri Lanka, Southeast Asia, and Brazil.

The symptoms and signs of TPE are attributed to trapping of microfilariae in pulmonary vasculature, with resultant eosinophilic alveolitis; patients develop paroxysmal cough and wheezing that is nocturnal and due to the nocturnal periodicity of the microfilariae, anorexia, and low-grade fever. Extreme eosinophilia (>3000/mm^3), high polyclonal IgE levels, elevations of antifilarial antibodies, and a therapeutic response to DEC establish the diagnosis.

THERAPY

DEC is recommended at 4 to 6 mg/kg/day for 14 days. Symptoms usually resolve within 1 week. Most patients are already being treated with corticosteroids, which can be tapered as patients recover. Up to 25% of treated patients relapse, requiring retreatment.

Loiasis

Also known as *African eyeworm*, loiasis results from infection with *Loa loa* acquired in the rain forests of West and Central Africa. After the bite of an infected tabanid (horse) fly, the parasites are inoculated into the subcutaneous tissue, where they mature and mate. The adults reside in subcutaneous tissue and migrate widely over the body. The microfilariae released into the blood by the adult female exhibit diurnal periodicity. These parasites do not contain *Wolbachia*.

Clinical manifestations differ between natives to endemic areas and newcomers. In the indigenous population, microfilaremia is generally asymptomatic, remaining subclinical until the adult migrates through the subconjunctival tissues of the eye or causes Calabar swellings, which are angioedematous lesions in the extremities (Figure 196.2). The swelling develops after the adult has migrated through the tissue, so biopsy is fruitless. Nephropathy, encephalopathy, and cardiomyopathy are rare. In nonresidents, allergic or hypersensitivity responses predominate and microfilaremia is rare, but Calabar swellings occur more frequently and are more debilitating. Peripheral blood eosinophilia, parasite-specific immunoglobulin G (IgG), and vigorous lymphocyte proliferation to parasite antigens are typical.

Definitive diagnosis requires either identification of microfilariae in peripheral blood or isolation of the adult worm. The microfilariae can be

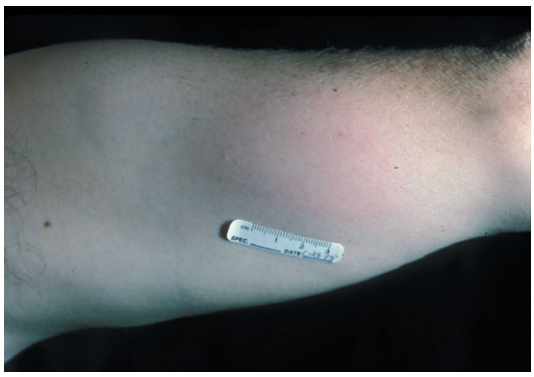

Figure 196.2 Calabar swelling of loiasis.

identified with the technique described for lymphatic filariasis. However, because the microfilariae of *Loa loa* exhibit diurnal periodicity, blood must be filtered between noon and 4 p.m. after the patient has been in the local time zone for 10 to 14 days. The adult worm is difficult to find unless it crawls across the eye. The worm is not found in Calabar swellings, and biopsy of these lesions is not indicated. In amicrofilaremic patients the diagnosis must be based on a characteristic history and clinical presentation, blood eosinophilia, and elevated levels of antifilarial antibodies.

THERAPY

The drug of choice to treat loiasis is DEC, which is effective against both the adult worm and microfilariae. It is dosed as 8 to 10 mg/kg/day (divided into three doses) for 21 days. A single course of therapy is curative in the majority of patients, although multiple courses may be required, and clinical relapses may occur up to 8 years following apparently successful treatment. It is not unusual for treated patients to develop localized inflammatory reactions such as subcutaneous papules or vermiform hives. These reactions, which are distinct from Calabar swellings, are a response to dying adult worms. The adult worms can be surgically extracted from these lesions, but removal is usually unnecessary.

Greater caution is warranted in patients who have microfilaremia. Treatment of such individuals with standard dosages of DEC has resulted in severe neurologic complications and even death caused by microfilariae in the central nervous system (CNS). In order to reduce the risk of developing treatment-induced encephalopathy, some experts have tried to reduce the microfilarial burden by performing apheresis of the blood before initiating treatment with DEC. In addition, gradual institution and escalation of DEC doses has been successful. DEC is gradually instituted, giving 0.5 mg/kg for the first dose then doubling every 8 hours until the full dose of 8 to 10 mg/kg/day (divided into three doses) is achieved. Prednisone (1 mg/kg/day) should be used during the first 3 to 6 days of treatment, and the first dose of prednisone should be given at least 6 hours before the first dose of DEC.

Since onchocerciasis occurs in the same geographic areas as loiasis and treatment of onchocerciasis with DEC can result in severe adverse effects, the clinician must rule out coinfection with onchocerciasis.

Other side effects of treatment are pruritus, fever, anorexia, lightheadedness, and hypertension. These symptoms usually resolve after the first few doses. A single course of DEC cures roughly half of those treated, and additional courses are frequently necessary to achieve cure. The decision to repeat treatment must be made on clinical grounds, since no objective laboratory data can predict treatment failures. Albendazole is an attractive treatment option for patients with high levels of microfilaremia: 200 mg twice daily for 3 weeks results in a gradual decline in microfilaremia over several months.

Once an individual has developed loiasis, prophylaxis should be considered if the patient returns to an endemic area. Once-weekly treatment with DEC is effective prophylaxis, but DEC is difficult to obtain in tropical countries since it is now manufactured only in the United States. Instead, albendazole 400 mg/day once weekly is an acceptable alternative.

Onchocerciasis

Infection with *O. volvulus* is the second leading infectious cause of blindness worldwide. Onchocerciasis occurs mainly in sub-Saharan Africa (where about 98% of the infected individuals live), and is found in savannah and rain forest. It is also found in Yemen and is scattered throughout Central and South America (Brazil, Colombia, Ecuador, Guatemala, Mexico, and Venezuela). Areas of transmission are focal because the *Simulium* blackfly vector flies only within a few kilometers of the streams where it breeds.

After the bite of an infected blackfly, larvae penetrate the skin and migrate into the subcutaneous tissue, where they mature into adults. About 7 to 36 months after infection, the gravid

Figure 196.3 Papular eruption in onchocerciasis.

female releases microfilariae, which migrate throughout the skin and concentrate in the dermis. There they can be ingested by female blackflies during their feeding to complete the life cycle. Most symptoms of onchocerciasis result from microfilariae migrating through host tissues, primarily the skin, lymph nodes, and eyes. As with the other filariases, clinical presentations differ between individuals from endemic and nonendemic areas. However, pruritus is the most frequent manifestation of onchocerciasis in all individuals. An itchy, erythematous, papular rash prominent early in the infection is also seen (Figure 196.3). With chronic infection there is epidermal atrophy, loss of elasticity with exaggerated wrinkling, and loose, redundant skin. The pigmentary changes have led to the term "leopard skin." Lymph node involvement, usually found in persons from endemic areas, presents as inguinal and femoral lymphadenopathy that may lead to enlargement of lymph nodes which hang down (so-called "hanging groin").

The most serious result of infection is blindness. It usually affects only individuals from endemic areas with moderate to heavy infections. Ocular complications occur more frequently with savannah strains, and the endosymbiont *Wolbachia* – found in some strains – appears to play an important role. Lesions may be found anywhere in the eye, and the most common early finding is conjunctivitis with photophobia. In the cornea, microfilariae in the anterior chamber cause punctate keratitis with "snowflake" opacities. In Africa, sclerosing keratitis, which may develop later, is the most common cause of blindness. Anterior uveitis and iridocyclitis occur in about 5% of infected Africans. In the Americas, secondary glaucoma may result from damage to the anterior uveal tract. Chorioretinal lesions, constriction of the visual fields, and frank optic atrophy may also develop.

Laboratory findings differ between persons from endemic and nonendemic areas. Eosinophilia and elevated polyclonal IgE are prominent findings in infected individuals. Eosinophilia and IgE levels are greater in natives of endemic areas, a finding that is contrary to the findings in the other filariases.

Like the other filariases, definitive diagnosis rests on the detection of an adult worm in an excised nodule or, more commonly, microfilariae in a skin snip. Skin snips are easily and bloodlessly obtained by sampling the most superficial skin layers using a corneoscleral punch. However, a 25-gauge needle may also be used to carefully tent up the skin while a scalpel is used to excise the most superficial layers of skin. The sample is incubated in saline or tissue culture medium on a glass slide or in a flat-bottomed microtiter plate at 37°C (98.6°F) for at least 2 hours.

THERAPY

Until recently, ivermectin remained the drug of choice for onchocerciasis and played a key role in onchocerciasis control programs. However, strains of *O. volvulus* relatively resistant to ivermectin were reported in 2004. Doxycycline exhibits significant macrofilaricidal activity by eliminating the bacterial endosymbiont *Wolbachia*, resulting in complete cessation of embyrogenesis for at least 18 months. A current recommended regimen consists of doxycycline, 100 to 200 mg/day for 6 weeks, with ivermectin 150 μg/kg given both during the last week of doxycycline therapy and again 3 to 4 weeks later.

For pregnant women and other persons for whom doxycycline is contraindicated, ivermectin is effective, given as a single dose of 150 μg/kg on an empty stomach. Because ivermectin alone does not kill adult worms, retreatment is usually required every 6 to 12 months for the life of the parasite (up to 14 years). More frequent administration (i.e., every 3–4 months) improves pruritus in symptomatic patients.

Reactions to ivermectin treatment are usually mild, occur within 3 days following treatment, and include transient pruritus, dizziness, headache, arthralgias, rash, or edema. More serious reactions are rare and have only been reported in patients who were coinfected with *Loa loa*.

Nodulectomy has been advocated as a way to decrease the parasitic load; however, two-thirds of nodules are inaccessible, being located deep in

the body. Priority is given to removing nodules on the head, which are associated with ocular complications.

Other filarial infections

Humans can harbor infections with other filariae, most notably *Mansonella* species: *Mansonella streptocerca*, *Mansonella perstans*, and *Mansonella ozzardi*. Most of these organisms are discovered incidentally, but occasionally, infected persons develop clinical manifestations of illness.

M. streptocerca, found in central Africa, is transmitted by biting midges. The major clinical manifestations resemble onchocerciasis, with pruritus, papular rashes, pigmentation changes, and inguinal adenopathy. Diagnosis is made by finding the characteristic unsheathed microfilariae in skin snips. As with onchocerciasis, treatment is with a single dose of ivermectin (150 μg/kg).

M. perstans, also transmitted by biting midges, is found in both central Africa and South America. The clinical manifestations resemble loiasis, with pruritus and transient angioedema, fever, headache, and arthralgias. Occasionally pericarditis and hepatitis occur. The diagnosis is established by the demonstration in the blood of the microfilariae; however, the worms do not exhibit periodicity. As with other filariases, eosinophilia and antifilarial antibodies are often seen. *Wolbachia* have been found in *M. perstans*; therefore, doxycycline 200 mg/day for 6 weeks is the drug of choice for this infection.

M. ozzardi is found only in Central and South America and the Caribbean. No clear picture of infection with this organism has been established, but symptoms and signs of disease attributed to this infection include headache, fever, arthralgias, hepatomegaly, adenopathy, pruritus, and eosinophilia. Diagnosis relies on finding the microfilariae in the peripheral blood, which circulate without periodicity. A single dose of ivermectin (6 mg) is effective.

Humans are accidental hosts for a variety of filariae that primarily infect small mammals. The parasite never completely develops, and the worms are usually found incidentally. The canine heartworm *Dirofilaria immitis* occurs mainly in the southeastern United States. The bite of an infected mosquito deposits the parasite, which develops in the subcutaneous tissues, then migrates to the pulmonary vasculature, where it is trapped and dies. It usually presents as a solitary pulmonary nodule that cannot be easily differentiated from other nonparasitic causes of pulmonary nodules. Eosinophilia is seen in fewer than 15% of infected persons and is only seen in the early stages of the lesion. Other *Dirofilaria* can cause discrete subcutaneous nodules. *Brugia* of small mammals can cause isolated lymph node enlargement in humans, but eosinophilia and antifilarial antibodies are uncommon. These zoonotic infections are diagnosed and cured by excisional biopsy.

DRACUNCULIASIS

Dracunculiasis is an uncommon infection in the tropics, usually in arid regions where populations bathe or wade in water used for drinking, such as step wells. The infection develops after consumption of water contaminated with water fleas infested with *Dracunculus medinensis* larvae. The larvae are released in the stomach, pass into the small intestine, and penetrate the mucosa, ultimately reaching the retroperitoneum, where they mature and mate. The infection remains largely asymptomatic until about a year later, when the female worm migrates to the subcutaneous tissues, usually in the legs. A tender papule forms and is occasionally associated with urticaria, dyspnea, nausea, and vomiting. The lesion develops into a vesicle that ruptures and ulcerates, exposing a portion of the gravid worm. On contact with water, large numbers of larvae are released and then ingested by crustaceans to complete the life cycle.

Therapy

Treatment of dracunculiasis has remained unchanged for thousands of years and consists of extraction of the emerging worm by securing the end to a small stick and gradually winding it a few centimeters daily until it is removed. Metronidazole (750 mg/day in three divided doses for 10 days) and thiabendazole (35 mg/kg twice daily for 3 days) have been used, although neither exerts any direct antiparasitic activity. Topical applications of hydrocortisone and tetracycline ointments have the same effect.

UNUSUAL TISSUE HELMINTH INFECTIONS

Visceral and ocular larva migrans

Visceral larva migrans (VLM) is a syndrome caused by nematodes that are normally parasitic to nonhuman hosts; thus, the larvae do not develop into adult worms and elicit eosinophilic inflammation as they migrate through human tissue. Most human infections are due to

Toxocara canis from dogs; less commonly, the syndrome can occur due to *Toxocara cati* from cats, and rarely *Ascaris suum* from pigs. VLM is seen mainly among preschool children, but most infections remain subclinical.

Humans acquire toxocariasis mainly by eating soil contaminated with the infective eggs shed in the stool of the host animal. VLM is usually asymptomatic, but those who seek medical attention present with fever, malaise, anorexia, weight loss, cough, wheezing, and rashes. Eosinophilia, the hallmark feature of VLM, may be striking. Hepatomegaly is typical, but splenomegaly is seen in only a minority. Neurologic involvement is uncommon, and death, which is even rarer, is due to severe brain, lung, or heart involvement. Serum antibodies to *Toxocara* larvae are a useful adjunct in establishing the diagnosis, but elevated titers are also found in patients without VLM.

Ocular larva migrans (OLM) is occasionally associated with clinically recognized VLM but is usually unaccompanied by systemic symptoms or signs. The typical patient is an older child that presents with unilateral visual deficits, ocular pain, leukocoria, or strabismus. In the early stages, the lesion is raised above the level of the retina and closely mimics retinoblastoma. After the acute phase has subsided, the lesion remains a well-defined circumscribed area of retinal degeneration. Serum antibodies to *Toxocara* larvae may be present, but because many patients with OLM have low or negative titers, they are unhelpful unless compared with titers in vitreous and aqueous humor, which are generally higher in affected patients.

Patients with serologic evidence of toxocariasis who have mild or no symptoms fall into the category of "covert" toxocariasis. Children with hepatomegaly, cough, sleep disturbance, abdominal pain, and headache are more likely to have elevated toxocaral antibody titers. Eosinophilia, when present, is often mild. Recurrent abdominal pain is often the sole presenting complaint. Adults can be affected as well, demonstrating nonspecific symptoms of weakness, pruritus, rash, difficulty breathing, and abdominal pain.

As with other tissue nematodes, the diagnosis of toxocariasis is made initially on clinical grounds, with confirmatory testing playing a secondary role.

THERAPY

The majority of patients with toxocariasis do not require treatment. Although generalized treatment recommendations are limited by a paucity of controlled clinical data, treatment is generally reserved for patients with severe disease. In patients with CNS, heart, or lung involvement, glucocorticoids should be considered to reduce inflammation. Although no conclusive studies have shown efficacy, albendazole 400 mg twice daily for 5 days is the currently recommended therapy for acute VLM. Alternatively, a 21-day course of mebendazole (20–25 mg/kg/day) has also been shown to be effective.

Albendazole has been found to be effective in OLM, but higher doses (adults, 800 mg BID; children 400 mg BID) have been used in these clinical studies. Treatment should extend 4 weeks, with concomitant glucocorticoids (0.5–1.0 mg/kg/day) for 2 to 4 weeks.

Figure 196.4. Cutaneous larva migrans.

Cutaneous larva migrans ("creeping eruption")

Cutaneous larva migrans (CLM), also known as "creeping eruption," is a zoonosis caused by animal hookworms, most often those of the dog (*Ancylostoma caninum*) or cat (*Ancylostoma braziliense*). As with human hookworms, the infection starts when the worm enters the skin from contaminated soil that is protected from desiccation and temperature extremes, as on beaches and under houses. As in toxocariasis, the worm cannot complete the infective cycle, so it continues to burrow through the subcutaneous tissues, resulting in the characteristic serpiginous, erythematous, elevated, and pruritic skin lesion (Figure 196.4). The worms may create tracks several centimeters in length per day. The infection is often seen in travelers who have walked barefoot on beaches frequented by roaming cats and dogs. Systemic symptoms and eosinophilia are rare.

THERAPY

Without treatment the lesions resolve spontaneously over 4 weeks, although patients are often miserable with pruritus. Treatment with a single dose of ivermectin (150 to 200 μg/kg on an empty stomach) or a 3-day course of albendazole (400 mg daily) has been shown to resolve the infection within 1 week, although retreatment is sometimes necessary.

Eosinophilic meningitis due to helminths

Eosinophilic meningitis due to infection with helminths is most often caused by the rat lungworm *Angiostrongylus cantonensis*, followed by the nematode *Gnathostoma spinigerum* and the raccoon ascarid *Baylisascaris procyonis*. However, the condition has been reported to be a consequence of infection with other helminths, specifically *Schistosoma japonicum*, *Paragonimus* species, and *Taenia solium* cysticerci. Eosinophilic meningitis occurs widely throughout Southeast Asia and the Pacific, including Hawaii, but is focally distributed in many other tropical areas worldwide.

Humans acquire angiostrongyliasis incidentally by eating raw infected mollusks, vegetables contaminated with mollusk slime, or marine fauna that have eaten the infected mollusks themselves, such as crabs and freshwater shrimp. Although nausea, vomiting, and abdominal discomfort may occur soon after eating the larvae, most patients have no symptoms until after an incubation period that ranges from 2 to 30 days (average about 2 weeks). At that time, patients develop an intermittent excruciating headache that may either be insidious or abrupt. Peripheral blood eosinophilia is prominent and lasts for about 3 months. Typical cerebrospinal fluid (CSF) findings consist of an elevated initial pressure, turbid fluid showing a pleocytosis with at least 10% eosinophilia, and elevated protein content but normal glucose. Diagnosis is based on the clinical findings, as recovery of the larvae from CSF or ocular fluids is rare. Treatment is mostly supportive. The headache responds poorly to analgesics and sedatives, but removal of CSF affords symptomatic relief and may be repeated as necessary. Corticosteroids have been tried in severe cases with some benefit. Because clinical deterioration and death can result from the inflammatory reaction to dying worms, anthelmintic therapy is likely contraindicated.

Infection with the raccoon ascarid *B. procyonis* causes a severe form of VLM usually associated with brain involvement and/or characteristic eye findings termed *diffuse unilateral subacute neuroretinitis* (DUSN). The developing worm can sometimes be found in the retina and killed by laser treatment. Albendazole treatment may be tried in persons with systemic disease, or if the larval worm cannot be found.

Figure 196.5. Angioedema of left hand in gnathostomiasis.

Gnathostoma, an intestinal parasite of dogs and cats, causes human infections in Southeast Asia, although foci of gnathostomiasis have been reported in Central and South America, southern and eastern Africa, India, and Australia. Humans acquire the parasite by eating undercooked freshwater fish that harbor the encysted larvae. In Asia, cases result from inadequately stored food from local restaurants. Gnathostomiasis is always associated with leukocytosis and hypereosinophilia. Intermittent subcutaneous swelling associated with nonpitting edema and pruritus is the most common manifestation (Figure 196.5), mimicking the Calabar swelling of loiasis. However, the most feared complication of gnathostomiasis is eosinophilic myeloencephalitis, which can be fatal; it begins as radicular pain followed by paralysis of the legs and urinary retention. Sudden onset of severe headache followed by coma and death may occur, usually without antecedent cutaneous swelling. The diagnosis of gnathostomiasis is usually established clinically. The only serologic test available is performed in Bangkok, Thailand, and samples can be sent via the CDC. Both albendazole (400 mg twice daily for 21–28 days) and ivermectin (200 mg/kg/day for 2 days) are effective. Occasionally, the worm will erupt from the skin shortly after treatment is initiated. Removal of the worm is both diagnostic and curative. Adjunctive treatment should include corticosteroids and adequate analgesia when indicated.

197. Schistosomes and other trematodes

James H. Maguire

The trematode flatworms that infect human beings include the schistosomes, which live in venules of the gastrointestinal or genitourinary tract, and other flukes that inhabit the bile ducts, intestines, or bronchi. The geographic distribution of each species of trematode parallels the distribution of the specific freshwater snail that serves as its intermediate host (Table 197.1). Schistosomes infect approximately 235 million persons worldwide; infections caused by the other flukes are more limited in distribution and number. Trematode infections last for years; most are subclinical, and in general only the small proportion of persons who have heavy worm burdens develops severe disease.

Table 197.1 Geographic distribution of important trematodes[a,b]

Schistostomes	
Schistosoma mansoni	South America, Caribbean, Middle East, Africa
Schistosoma japonicum	China, Philippines, Indonesia, Thailand
Schistosoma mekongi	Cambodia, Laos
Schistosoma intercalatum, *Schistosoma guineensis*	West and Central Africa
Schistosoma haematobium	Africa, Middle East
Biliary and liver flukes	
Clonorchis sinensis	China, Taiwan, Korea, Japan, Vietnam
Opisthorchis viverrini	Thailand, Laos, Cambodia
Opisthorchis felineus	Eastern Europe, former Soviet Union
Fasciola hepatica	Europe, North Africa, Asia, western Pacific, Latin America
Lung flukes	
Paragonimus westermani and other species	Far East, South Asia, Philippines, Central and South America, West Africa, Mississippi River Basin (USA)
Intestinal flukes	
Fasciolopsis buski	Far East
Heterophyes heterophyes	Far East, Egypt, Middle East
Metagonimus yokogawai	Far East
Nanophyetus salmincola	Pacific Northwest

[a] Parasites may be limited to certain countries in the regions listed and certain foci within these countries.

[b] Many less common trematodes that infect human beings are not listed here.

SCHISTOSOMIASIS

Clinical presentation

A history of contact with possibly infested freshwater in an endemic area should prompt an evaluation for schistosomiasis, even in the absence of symptoms (Figure 197.1). Clinical manifestations that suggest the diagnosis vary according to the stage of infection. Some persons complain of intense pruritus or rash shortly after the infective cercariae penetrate the skin. Previously uninfected visitors to endemic areas may develop acute schistosomiasis, or Katayama fever, 2 to 12 weeks after exposure, as the immune system responds to maturing worms and eggs. Symptoms range from mild malaise to a serum sickness-like syndrome that lasts for weeks and may be life-threatening. Common features include fever, headache, abdominal pain, myalgia, dry cough, diarrhea, hepatosplenomegaly, lymphadenopathy, urticaria, and marked eosinophilia.

Chronic infections with schistosomes usually are asymptomatic; slight or moderate eosinophilia occurs frequently. Long-term residents of endemic areas may harbor heavy infections for long periods and thus are more likely than transient visitors to have symptoms. Disease results from egg deposition in tissues and the ensuing inflammatory and fibrotic response (Figure 197.2). In infections due to *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, *Schistosoma intercalatum*, and *Schistosoma guineensis*, involvement of the bowel leads to mucosal inflammation and microulcerations, diarrhea, bleeding, polyps, and strictures. Embolization of eggs to the liver results in hepatosplenomegaly, periportal fibrosis, portal hypertension, and esophageal varices. Hematuria and dysuria are early symptoms of chronic infection by *Schistosoma haematobium;* later, fibrosis and calcification

of the bladder and lower ureters results in hydroureter and hydronephrosis (Figure 197.3), and squamous cell carcinoma of the bladder may develop. Ectopic deposition of eggs in the skin, genitalia, and other organs occurs during both the acute and chronic stages of infection. Transverse myelitis, seizures, and other serious sequelae result from egg deposition in the central nervous system. In endemic areas, chronic infections of even moderate intensity have been associated with anemia, poor nutritional status, and cognitive impairment.

Diagnosis

The most direct method of diagnosis is microscopic examination of stool or urine for schistosome eggs (Figure 197.4). Because egg output is low in light infections, concentration techniques and examination of several specimens obtained on different days should be routine. Eggs should be counted to estimate the intensity of infection and to monitor the response to therapy. Counts above 400 eggs per gram of feces or 10 mL of urine are considered heavy and are associated with higher rates of complications. Microscopic examination of snips of rectal mucosa obtained

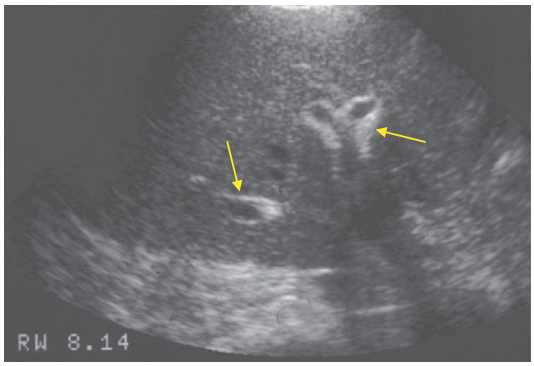

Figure 197.5 Ultrasound of the liver showing periportal fibrosis. Two portal tracts (one of the tracks is bifurcated) are surrounded with an area of increased echo (*arrows*).

at proctoscopy may reveal eggs when stool examination is negative.

Serologic tests for antibodies to schistosomes are available at commercial laboratories in the United States and at the Centers for Disease Control and Prevention (CDC) in Atlanta. The CDC uses a sensitive and specific Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) for screening and a highly specific immunoblot for confirmation and species determination. These tests cannot distinguish active from past infections but are useful for the diagnosis of acute schistosomiasis before eggs are shed in the stool. Serologic tests should be used to screen previously unexposed travelers and expatriates; a positive serologic test is presumptive evidence of infection even if subsequent microscopy is negative.

Persons with confirmed infections due to the intestinal schistosomes should be evaluated with measurement of liver function tests and tests for chronic hepatitis B and C to rule out concomitant hepatocellular disease. Heavy infection or evidence of liver disease should prompt an ultrasound to document periportal fibrosis and signs of portal hypertension (Figure 197.5). Esophageal varices are visualized by barium swallow or endoscopy. Urinalysis, urine culture, and serum creatinine determination are indicated for persons with *S. haematobium* infection. Ultrasonography or other imaging studies detect complications such as hydronephrosis, polyps, stones, and carcinoma of the bladder.

Table 197.2 Treatment of trematode infections

Parasite	Drug of choice	Dosage
Schistosoma mansoni, *S. haematobium*, *S. intercalatum*, S. *guineensis*[a]	Praziquantel	40 mg/kg/d in 2 doses ×1 d
Schistosoma japonicum, *S. mekongi*	Praziquantel	60 mg/kg/d in 2 or 3 doses ×1 d
Clonorchis sinensis, *Opisthorchis* spp.	Praziquantel	75 mg/kg/d in 3 doses ×1 d
Fasciola hepatica, *F. gigantica*	Triclabendazole	10 mg/kg ×1 or 10 mg/kg × 2 doses 6 h apart
Paragonimus spp.	Praziquantel	75 mg/kg/d in 3 doses ×2 d
Fasciolopsis buski, *Heterophyes heterophyes*, *Metagonimus yokogawai*	Praziquantel	75 mg/kg/d in 3 doses ×1 d
Nanophyetus salmincola	Praziquantel	60 mg/kg/d in 3 doses ×1 d

[a] To increase the likelihood of a complete cure, praziquantel 60 mg/kg/day in 2 or 3 split doses can be given to persons with schistosomiasis who have left an endemic area. Many experts suggest that persons who acquired *S. mansoni* infection in Africa should also receive 60 mg/kg/day in 2 or 3 split doses.

Therapy

All persons with schistosomiasis should receive treatment. Eradication of infection is desirable because even a single pair of worms may deposit eggs in the central nervous system. In endemic areas where reinfection is inevitable, the goal is to reduce worm burdens to levels that are unlikely to produce disease. Successful treatment not only prevents complications but also may cause regression of polyps and fibrotic lesions. Fortunately, the treatment of choice, praziquantel, is safe and highly effective after one or a few oral doses (Table 197.2).

Praziquantel causes an influx of calcium ions across the tegument of the adult worm, leading to a tetanic contraction and vacuolization of the tegument that makes the parasite susceptible to immune destruction. Cure rates range from 65% to 95%, and in persons not cured, egg excretion is reduced by >90%. A few reports suggest that resistance to praziquantel may be developing. Adverse effects, which are usually mild and last less than 24 hours, may be caused by reactions to dying worms rather than drug toxicity. Patients occasionally report malaise, headache, dizziness, or abdominal discomfort. Nausea, vomiting, diarrhea, bloody stools, fever, and urticaria are uncommon. The World Health Organization has judged praziquantel safe for pregnant or lactating women. Persons with known or suspected cysticercosis should remain under observation during therapy because of the risk of seizures or other neurologic consequences of dying cysticerci. Praziquantel is metabolized in the liver, and the dosage need not be reduced because of renal insufficiency.

Severely ill persons with acute schistosomiasis should receive corticosteroids as well as praziquantel, although there is controversy about timing of anthelmintic therapy. Some experts recommend delaying praziquantel treatment because maturing schistosomes are less susceptible to praziquantel than are adult worms, corticosteroids lower serum levels of praziquantel, and acute illness may be exacerbated by reactions to killing of parasites. Because of the risk of ectopic infection, we favor administration of praziquantel shortly after administration of steroids. All patients should receive a second course of treatment 4 to 6 weeks after the first. Artemisinin derivatives have activity against immature parasites, but although they can be effective in preventing infection, their utility in the management of acute schistosomiasis is uncertain.

Because antischistosomal drugs may temporarily inhibit egg laying by adult worms, stool and urine should be examined 3 and 6 months after completion of therapy. Eosinophilia, hematuria, and other symptoms that persist beyond this time should prompt repeat parasitologic studies and evaluation for causes other than schistosomiasis. Serologic tests may remain positive for years after successful treatment and are of limited utility for the assessment of cure.

OTHER TREMATODE INFECTIONS

More than 70 species of trematodes other than schistosomes infect 65 million or more persons worldwide. Most are parasites of wild and domestic animals. Human beings become infected by ingestion of metacercariae encysted in freshwater fish, crustacea, and plants, the second intermediate hosts.

Clonorchiasis and opisthorchiasis

The oriental liver flukes *Clonorchis sinensis*, *Opisthorchis viverrini*, and *Opisthorchis felineus* inhabit the biliary tree of persons who ingest

infected carp and other freshwater fish without proper cooking. Most patients are asymptomatic, but eosinophilia is common. An acute illness resembling Katayama fever occasionally occurs 2 to 3 weeks after initial exposure. Persons with heavy infections for many years develop symptoms due to irritation and inflammation of biliary epithelium. Patients complain of right upper quadrant discomfort, anorexia, and weight loss. On physical examination the liver is palpable and firm. Cholangitis, pancreatitis, and cholangiocarcinoma are infrequent complications.

Diagnosis is made by finding eggs in the stool (Figure 197.4) or identifying adult worms during endoscopic retrograde cholangiopancreatography (ERCP) or surgery for complications. In symptomatic cases, ultrasonography or computed tomography (CT) demonstrates dilation and stricture of bile ducts, thickening of the gallbladder wall, and stones. A single course of praziquantel eradicates infection in more than 85% of cases (Table 197.2). An alternative is albendazole for 7 days.

Fascioliasis

Infection with the sheep liver fluke *Fasciola hepatica* and the closely related *Fasciola gigantica* results from ingestion of uncooked watercress or other aquatic vegetation from sheep- and cattle-raising parts of the world. After excysting in the duodenum, immature worms pass through the bowel wall and peritoneal cavity, invade the liver, and burrow through the parenchyma to the bile ducts. This migration provokes an acute syndrome of fever, nausea, tender hepatomegaly, eosinophilia, and urticaria lasting weeks to months. Aberrant migration causes nodules in the skin, painful inflammation of the intestinal wall, pleural effusion, or lesions in the lungs, brain, or elsewhere. Chronic fascioliasis is usually subclinical, but some persons have symptoms due to inflammation and obstruction of bile ducts.

Diagnosis is confirmed by demonstrating eggs in samples of stool, bile, or duodenal aspirates (Figure 197.4) or by recovering worms at surgery. Serologic tests are useful during acute infection because symptoms develop 1 to 2 months before eggs appear in the stool. Ultrasonography and ERCP may demonstrate adult worms and biliary pathology, and CT or magnetic resonance (MR) shows migratory hypodense lesions in the liver corresponding to necrosis along the path of larval migration.

Treatment of fascioliasis is with one or two doses of the veterinary drug triclabendazole which is available from Victoria Pharmacy in Zurich, Switzerland (Table 197.2). Given with food, treatment is successful in approximately 80% of cases, and a repeat course cures most of the remaining cases. The alternative, nitazoxanide, is less effective, and fascioliasis responds poorly to praziquantel.

Paragonimiasis

Infection with *Paragonimus westermani*, the oriental lung fluke, and, less commonly, other species of *Paragonimus*, follows ingestion of raw or poorly cooked freshwater crabs or crayfish. An acute phase with fever, abdominal and chest pain, cough, and eosinophilia corresponds to migration of immature parasites through the bowel wall, diaphragm, and pleura en route to the lungs. The inflammatory reaction to adults encapsulated in the lungs and the shedding of eggs into the bronchial tree are responsible for chronic symptoms. Patients complain of cough, rusty or golden sputum, hemoptysis, vague chest pains, and dyspnea on exertion. Radiographs of the chest show poorly defined infiltrates, cysts, nodules, cavities, calcified lesions, and pleural effusions that on aspiration are seen to contain eosinophils. The findings may suggest tuberculosis. Bronchiectasis, bacterial pneumonia, or empyema complicates heavy infections. Extrapulmonary migration of flukes causes migratory subcutaneous nodules, involvement of abdominal viscera, or focal lesions of the central nervous system. Cerebral paragonimiasis is characterized by headache, seizures, focal neurologic deficits, cerebrospinal fluid eosinophilia, and cystic lesions on radiographs and scans.

Paragonimiasis is diagnosed by identifying expectorated eggs in the sputum, swallowed eggs in the feces, or worms and eggs in biopsy specimens (Figure 197.4). Several examinations of stool and sputum may be necessary. Serologic tests, such as the immunoblot offered by the CDC, are useful for diagnosis of early, light, and extrapulmonary infections.

The treatment of choice for paragonimiasis is praziquantel or alternatively, triclabendazole (Table 197.2). Because the inflammatory reaction to dying worms may precipitate seizures or other neurologic complications, corticosteroids should be used simultaneously with praziquantel for cerebral paragonimiasis.

Intestinal fluke infections

Adult intestinal flukes live attached to the mucosa of the duodenum and jejunum, where they cause local inflammation and ulceration. Of the dozens of species that infect human beings, *Fasciolopsis buski*, the giant intestinal fluke, is the best known. Infection is acquired by eating uncooked aquatic plants, such as water caltrop, water chestnut, and watercress. Heavily infected persons develop hunger pains that suggest peptic ulcer, diarrhea with mucus, and in extreme cases, malabsorption, ascites, anasarca, and intestinal obstruction. Eosinophilia is common.

Other important intestinal flukes include *Heterophyes heterophyes* and *Metagonimus yokogawai*, both of which are acquired by ingestion of raw or undercooked freshwater fish. Symptoms caused by these parasites resemble those produced by *Fasciolopsis*, but embolization of eggs that enter the circulation may cause severe myocarditis or cerebral hemorrhage. *Nanophyetus salmincola* is transmitted in the Northwest United States by ingestion of raw or undercooked salmon or trout. Manifestations include abdominal pain, watery diarrhea, and eosinophilia.

The diagnosis of all intestinal fluke infections is made by demonstrating eggs in the feces. Because the number of eggs excreted may be low, concentration techniques and repeated examinations are recommended. Praziquantel is the drug of choice (Table 197.2). Alternatives include triclabendazole and, for *Fasciolopsis* and *Heterophyes* infections, niclosamide.

198. Tapeworms (cestodes)

Zbigniew S. Pawlowski

Cestodes cause intestinal (e.g., taeniasis, hymenolepiasis) and/or tissue parasitoses (e.g., cysticercosis, echinococcosis). Most of intestinal tapeworm infections are meat-borne zoonoses, whereas tissue infections with larval cestodes are fecal-borne, acquired mainly through ingestion of the tapeworm eggs from human, dog, or fox feces.

TAENIA SAGINATA AND *TAENIA ASIATICA* TAENIASIS

Taenia saginata, the beef tapeworm, sometimes >5 m long, may live up to 30 years in the small intestine of humans, who are its only natural host. Humans are infected by ingestion of the cysticercus, a bladder worm <1 cm in diameter, present in raw or undercooked beef.

Taenia saginata infections can spread easily because of a high fecundity of the tapeworm (>500 000 eggs produced daily for years), wide and long-term contamination of the environment with eggs, bovine cysticercosis that may escape routine meat inspection when of a low intensity, and, finally, common consumption of raw beef. More than 10% of nomads are infected in East Africa; in Europe the annual incidence in urban populations is <0.1%; in the United States and Canada, *T. saginata* taeniasis is uncommon and observed mainly among migrants from Latin America.

Taenia saginata infection occurs mainly in well-nourished middle-aged individuals who are raw beef eaters. Complaints include vague abdominal pains, nausea, weight loss or gain, and some perianal discomfort caused by gravid proglottids (about six per day) crawling actively out of the anus. Sometimes, the patient passes a longer part of tapeworm strobila; in that case the expulsion of proglottids may stop for some weeks. The diagnosis is set up by questioning and macroscopic examination of expulsed tapeworm proglottids. *Taenia* eggs are found more often on anal swabs than in feces. Tests detecting parasite antigen in feces are highly sensitive and specific and may detect the infections even when proglottids or eggs are not expelled.

Treatment of *T. saginata* taeniasis with praziquantel or niclosamide is safe and effective in 95% and 80% of cases, respectively. Praziquantel is given orally in a single dose of 5 to 10 mg/kg an hour after a light breakfast. Niclosamide is preferred for children younger than 4 years and for pregnant women. Niclosamide (use only the original products, recently manufactured) should be chewed thoroughly on an empty stomach in a single dose of 2 g for adults, 1 g for children who weigh 10 to 35 kg, and 0.5 g for smaller children. For both drugs adverse effects, such as abdominal discomfort, headache, and dizziness, are rare and transient. Tapeworm is usually expelled in fragments within a few hours; the scolex, indicating elimination of the entire worm, is often difficult to find. Therefore, successful therapy can be confirmed only when no proglottids reappear within 4 months after treatment.

Taenia asiatica, described recently in several Asian countries, is a sister species of *T. saginata*, similar morphologically but a distinct species when examined by molecular techniques. Its life cycle is different; small cysticerci develop in liver and viscera of pigs and a range of wild animals. Humans become infected by eating raw viscera, especially liver, of the infected animals. The diagnosis and treatment are similar to *T. saginata. Taenia asiatica* and *T. saginata* do not produce cysticercosis in humans.

TAENIA SOLIUM TAENIASIS AND CYSTICERCOSIS

Taenia solium (pork tapeworm) infection is common in Latin American countries, Central and South Africa, India, Indonesia, and China. Intestinal infection is acquired by eating undercooked pork containing cysticerci. Cysticercosis,

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

a cystic larval form developing in the tissues, is acquired by ingesting *T. solium* eggs present in contaminated food or water or on hands spoiled with feces (autoinfections or family infections are not uncommon). Human cysticercosis may be common in endemic countries; sporadic cases of cysticercosis are diagnosed in humans in the United States and in Europe, having been acquired abroad or from immigrants infected with *T. solium* tapeworm.

The pork tapeworm is smaller than *T. saginata*, and its proglottids are usually expelled with feces, starting 2 months after ingestion of infected pork. Clinical symptoms and signs of taeniasis are not characteristic and are similar to *T. saginata* infection. The diagnosis is made by examination of the expelled proglottids or detecting the specific coproantigens. Finding *Taenia* eggs in feces can only confirm the diagnosis of taeniasis (*T. solium* eggs are morphologically indistinguishable from those of *T. saginata*). Proglottids and feces should be handled with care because *T. solium* eggs are infective for humans.

Treatment of *T. solium* taeniasis is mandatory as soon as possible, in both confirmed and suspected cases, due to a danger of spreading eggs causing cysticercosis in humans or pigs. Treatment of intestinal infection is the same as for *T. saginata* taeniasis; rarely, praziquantel may provoke symptoms in concomitant asymptomatic cysticercosis. Evaluation of treatment is by frequent fecal examination for *Taenia* eggs or coproantigens during the second and third months after anthelmintic therapy.

In cysticercosis, *T. solium* cysticerci may be localized in muscle and subcutaneous tissues (Figure 198.1A) without much symptomatology; the clinically important are mainly the cases of

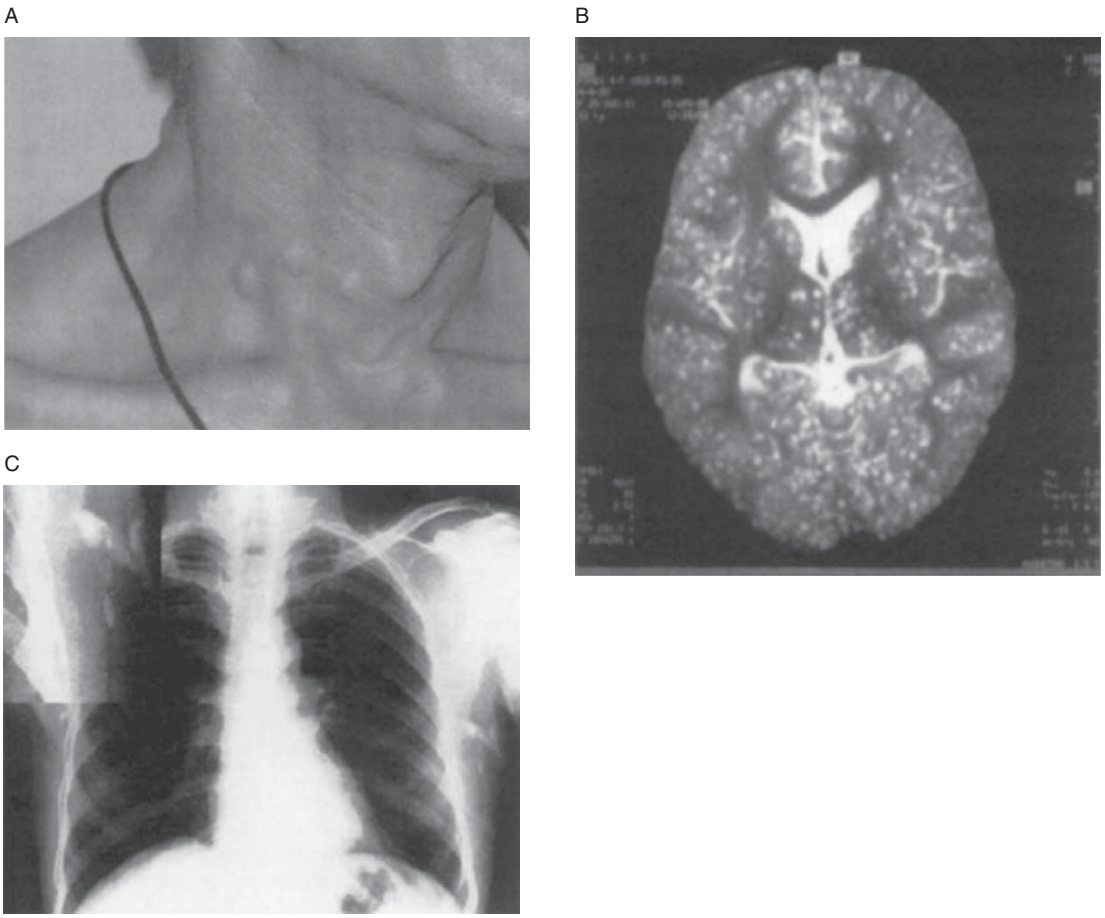

Figure 198.1 Cysticerci in subcutaneous location **(A)**, on brain computed tomography (CT) showing innumerable cysticerci (starry-night appearance) **(B)**, and calcifications in soft tissues **(C)**. (Courtesy of Dr. S. K. Gaekwed.) Bradley's *Neurology in Clinical Practice*, 4th edn. Butterworth-Heinemann; 2004.

neurocysticercosis, ocular cysticercosis, and heart cysticercosis. Neurocysticercosis is suspected when epileptiform seizures (70% to 90% of cases), intracranial hypertension, or psychiatric disturbances occur, especially in adolescents or adults in endemic areas or having contact with a *T. solium* carrier (household infection is common). The most malignant forms of cysticercosis are at ventricular and basal cisternal parasite localizations. If subcutaneous nodules are present (which is uncommon, except in India), the final diagnosis can be made by biopsy demonstrating a scolex or typical structures of cysticercus wall. Most often, cysticerci are diagnosed by finding cysticercus-like structure(s) in the brain, spine, eye, or heart by computed axial tomography (CAT) or magnetic resonance imaging (MRI) scans (Figure 198.1B). In some cases the inflammatory reaction or edema and ventricular dilatation are present. In ocular cysticercosis the diagnosis can be made by ophthalmoscopy. Less often cysticercosis is suspected on the basis of ultrasound scanning and/or x-ray examination, particularly if calcifications are present (Figure 198.1C). Positive serologic tests, especially enzyme immunoassay (EIA) and enzyme-linked immunoelectrontransfer blot (EITB) assays, support the clinical diagnosis but cannot differentiate between active and past infections.

Neurocysticercosis is often asymptomatic; in such cases, indications for treatment must be considered carefully. Symptomatic cases can be active or inactive (calcified). Therapy can be via specific anthelmintic treatment, surgery, corticosteroids, or symptomatic treatment. The choice of treatment has to be individually tailored. Anthelmintic therapy with praziquantel or albendazole is indicated in active cysticercosis with several parenchymal cysts or with clinical signs of vasculitis, encephalitis, and arachnoiditis. Traditionally, praziquantel is given orally in a daily dose of 50 mg/kg for 14 days, but a shorter regimen with a higher dose has been proposed. Albendazole is given orally in a daily dose of 15 mg/kg for 8 days. For parenchymal brain cysticerci, the efficacy is about 60% for praziquantel and 85% for albendazole. Damage to cysticerci, caused by both drugs, may result in a local inflammatory reaction and edema, which necessitates a concomitant additional corticosteroid or antihistamine drug therapy.

Surgical extirpation is indicated for single parenchymal, intraventricular, spinal, and ocular cysticerci and with focal symptoms (e.g., cranial nerve dysfunction). A ventricular shunt is indicated in hydrocephalus. Corticosteroids and immunosuppressants may control vasculitis and encephalitis. Antiepileptic drugs are used mainly in inactive cysticercosis with granulomatous or calcified lesions. The global disability and mortality from neurocysticercosis are still considerable but its control measures are introduced only locally.

HYMENOLEPIS NANA INFECTIONS

Hymenolepis nana, the dwarf tapeworm, 15 to 40 mm long, lives only up to 3 months in human small intestine. Some of the tapeworm eggs are expelled with feces and constitute a source of autoinfection or infection for other people. The other eggs hatch in the human intestine and develop within a month into cysticercoids in intestinal villi and later into the next generation of adult tapeworms in the same host.

Such a cycle facilitates spread of infection in close communities (day-care centers, schools, psychiatric institutions) as well as permits intensive infections of thousands of tapeworms, especially in malnourished or immunodeficient individuals. Usually a specific immunity develops and regulates the intensity and duration of infection, which occurs mainly in children and often clears spontaneously in adolescence. Hymenolepiasis is very common in regions with a hot, dry climate; it is rare in countries with appropriate sanitation.

Intensive infections may cause diarrhea, abdominal pains, and general symptoms such as weight loss, pallor, and weakness. Diagnosis is made by finding characteristic *H. nana* eggs in feces. Treatment with a single dose of praziquantel, 15 to 25 mg/kg, is highly effective; in intensive infections treatment must be repeated after 3 weeks. Niclosamide is much less effective and requires repeated courses of 7 days with the daily dose of 2 g for adult patients. Successful treatment has to be confirmed by negative fecal examination every 2 weeks for 2 months after therapy.

OTHER INTESTINAL CESTODES

Diphyllobothriasis, caused by *Diphyllobothrium latum*, *Diphyllobothrium dendriticum*, and *Diphyllobothrium pacificum*, still occurs around unpolluted large lakes in moderate climates (the Great Lakes in the United States and Canada and lakes in Finland and Switzerland) and along the Pacific Coast in South America. An uncommon clinical

complication of diphyllobothriasis is vitamin B_{12} deficiency. Diagnosis is made by finding characteristic eggs during fecal examination. Treatment is a single dose of praziquantel, 15 to 25 mg/kg. Evaluation of successful therapy is by repeated fecal examination some months after.

Hymenolepis diminuta (rat tapeworm) and *Dipylidium caninum* (dog tapeworm) infections occur accidentally in humans and are usually nonintensive and asymptomatic. They are diagnosed by fecal examination and can be easily treated by a single dose of praziquantel, 15 mg/kg.

Spirometra spp., a tapeworm parasitizing a broad spectrum of amphibian hosts, reptiles, birds, and mammals, occur sporadically but worldwide. It causes sparganosis, larval worm infection, mainly in the subcutaneous tissue or in an orbit.

CYSTIC ECHINOCOCCOSIS (HYDATID DISEASE)

Echinococcus granulosus is a tiny tapeworm living in the small intestine of some carnivores, mainly dogs. *Echinococcus granulosus* eggs, which are excreted in dog feces and contaminate an environment, are the source of cystic echinococcosis in various animals, mainly sheep or pigs, and sporadically in humans. Echinococcosis is still common in sheep-breeding regions in South America, Mediterranean countries, Middle East, Central Asia, and China. Small enzoonotic foci are found in Alaska, California, southern Utah, northern Arizona, and New Mexico. In Europe, sporadic cases of cystic echinococcosis are frequently caused by an *E. granulosus* strain, originating from pigs.

Echinococcus cysts develop mainly in the liver (about 65%) or lungs (25%), but they can invade any tissue, including the brain, kidney, spleen, heart, and bone. Clinical manifestations are diverse, depending on location, size, and number of the cysts as well as the complications resulting from cyst rupture and communication with biliary or bronchial systems or with adjacent body cavities. Bacterial infection of the cysts and secondary peritoneal echinococcosis are not uncommon. Clinical diagnosis is confirmed mainly by imaging techniques (sonography, CT, MRI, positron emission tomography [PET], and/or x-ray examination. Classification of cystic echinococcosis in sonography is based on cyst morphology, considering also fertility and the content of the cyst; one can differentiate a cystic lesion (CL) stage, similarly to nonparasitic cysts, and C1 to C5 stages from young active cysts to old inactive cysts. Diagnosis can be confirmed by the serologic tests (sensitive enzyme-linked immunosorbent assay [ELISA], followed by more specific immunodiffusion or immunoblot tests). In some cases the clinical picture, imaging, and serology are not conclusive, and the final diagnosis is made by finding parasite hooks, protoscolices, or cyst wall fragments in sputum or in biopsy, surgical, or necropsy samples. In some specialized centers, cyst puncture with a fine needle guided by sonography and performed under the cover of albendazole is becoming widely used. Most commonly the differential diagnosis considers liver simple nonparasitic cysts.

The echinococcus cysts may be sterile or fertile (with protoscolices), simple or multiple, small or large (up to 20 cm in diameter), asymptomatic or symptomatic, active or inactive, complicated or noncomplicated. The choices of management are surgery, chemotherapy, PAIR (puncture, aspiration, injection of a cysticidal substance, and reaspiration), or observation without any intervention. Major indications for surgery are large, active, superficially located, and easy-to-rupture liver cysts and most of the brain, spinal, heart, and bone cysts. Surgery can be radical (removal of the whole intact cyst) or conservative (cystectomy and removal of the parasite but not the host pericyst). Surgery brings a risk of complications, such as anaphylactic shock or secondary echinococcosis and death (0.5% to 4%).

Chemotherapy is used more widely, mainly but not exclusively in inoperable cases. An important indication for chemotherapy before surgery or a puncture is prevention of secondary echinococcosis due to unintentional spillage of a cyst's contents. The drugs used are mebendazole, 40 to 50 mg/kg daily for at least 3 months, or albendazole, 10 to 15 mg/kg daily for at least 1 month. Sometimes repeated courses of treatment are necessary. Chemotherapy with both drugs brings a risk of embryotoxicity in early pregnancy. Careful clinical monitoring can prevent hepatotoxicity, neutropenia, and thrombocytopenia but not alopecia, which may occur.

PAIR is used in endemic regions with poor healthcare facilities. Unfortunately, no protoscolicide is both effective and safe; widely used now are 75% to 95% ethanol, 20% hypertonic sodium chloride solution, and 0.5% cetrimide. Formalin solution should no longer be used, as it can provoke sclerotic cholangitis.

ALVEOLAR AND POLYCYSTIC ECHINOCOCCOSIS

Echinococcus multilocularis tapeworms develop in the intestine of some carnivores, mainly foxes, but also dogs; the intermediate hosts are rodents such as voles, lemurs, and mice. Large natural enzoonotic foci of alveolar echinococcosis are in the Northern Hemisphere, especially the region of the Alps (France, Switzerland, Germany, Austria), Siberia, northern Japan, and Alaska. Humans are infected accidentally by *E. multilocularis* eggs present in fecally polluted natural environments (water, soil, berries) or on fox's skin or dog's hair.

Incidence of human alveolar echinococcosis varies between 0.02 and 0.18 per 100 000 inhabitants. However, a spread of *E. multilocularis* is observed in Europe westward (France), eastwards (Poland and Lithuania), northwards (Norway and Sweden), and southwards (northern Italy). In addition to its natural foci it spreads, together with foxes, in some urbanized areas.

Echinococcus multilocularis lesions, composed of clusters of tiny vesicles, usually begin in the liver, grow slowly over the years in a tumorlike pattern, and may metastasize to lungs and brain. Modern (PNM) classification of alveolar echinococcosis lesions in liver is based on the size of parasitic mass, involvement of the neighboring tissues, and distant metastases. The early clinical manifestations are usually vague; the advanced disease is invariably symptomatic due to liver lesions or lung or brain metastases. Diagnosis is based on imaging techniques and molecular and immunologic tests; the latter (e.g., Em2G11) are highly specific. The differential diagnosis is mainly with neoplasma conditions. Treatment is by radical surgical resection of liver lesions followed by at least 2 years of chemotherapy. Recurrent or nonresectable lesions require lifelong chemotherapy with mebendazole or albendazole, which are parasitostatic rather than parasitocidal. Nitrazoxanide and amphotericin B are now suggested as potential alternative additional or combined drugs. The treatment has to be performed in specialized centers because of various and frequently severe complications, which may need another surgery or in rare cases a liver transplantation.

Polycystic echinococcosis occurs in humans in Central and South America and is caused by *Echinococcus vogeli* and *Echinococcus oligartrus*, the parasites of wild mammals. The numerous small cystic lesions can be found in the liver, lungs, abdominal cavity, stomach, heart, and orbit. The clinical course is similar to alveolar echinococcosis. Polycystic echinococcosis frequently requires surgery and responds well to albendazole.

199. *Toxoplasma*

Roderick Go and Benjamin J. Luft

Toxoplasmosis, caused by the obligate intracellular parasite *Toxoplasma gondii,* is responsible for significant morbidity and mortality throughout the world. Although it has long been recognized as a serious congenital disease, it is only with the advent of acquired immunodeficiency syndrome (AIDS) and the increased use of immunosuppressive therapy that toxoplasmosis has reached epidemic proportions.

Humans are incidental hosts in the life cycle of *T. gondii*. Acute infection occurs via ingestion of meats or water contaminated with tissue cysts or tachyzoites or by handling cats, the definitive host. Once the human host develops an adequate immune response, tissue cysts are formed and a chronic or latent infection ensues. Antibodies against *T. gondii* will be present in serum for life. When a chronically infected person becomes immunocompromised, particularly with defects in cell-mediated immunity, devastating reactivation of the latent infection may occur.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In the immunocompetent host, primary infection is often asymptomatic. Acute infection can mimic the symptoms of mononucleosis with a common manifestation of cervical or occipital lymphadenopathy. The lymph nodes usually are nontender, are nonsuppurative, and persist for less than 4 to 6 weeks. Infrequently, toxoplasmosis can lead to myocarditis, hepatitis, polymyositis, pneumonitis, and encephalitis.

Toxoplasmosis in the immunocompromised patient is most commonly manifested by toxoplasmic encephalitis (TE), usually alone but sometimes as part of a multiorgan infection. Isolated organ involvement without central nervous system (CNS) disease is uncommon. In the AIDS patient, TE usually develops when the CD4 lymphocyte count falls below $100/mm^3$, although the risk of developing overt infection begins when CD4 counts fall below $200/mm^3$. The clinical manifestations of TE are protean, including signs and symptoms of focal or generalized neurologic dysfunction or more commonly both, depending on the number, size, and location of the lesions. Cerebral edema, vasculitis, and hemorrhage, which can accompany active infection, also contribute to the disease process. Toxoplasmic encephalitis most commonly presents with a subacute onset of focal neurologic deficits with or without evidence of generalized cerebral dysfunction. Less often, seizures are the initial manifestation. Occasionally, signs and symptoms of generalized cerebral dysfunction dominate the presentation, and patients develop focal deficits as the infection progresses. The clinical presentation varies from an insidious process evolving over several weeks to a more acute or even fulminant course. Headaches may be focal or generalized and unremitting.

Serologic tests for diagnosis of toxoplasmosis in AIDS patients are useful only to identify human immunodeficiency virus (HIV)-infected individuals at risk for development of TE and as support for the diagnosis in AIDS patients with focal brain lesions. The Sabin–Feldman dye test is the accepted standard for measurement of immunoglobulin G (IgG) antibodies, which have been shown to be higher in AIDS patients with TE than in those without TE. The immunofluorescence assay (IFA), which is more commonly used, measures the same IgG antibodies as the dye test. Almost all AIDS patients with TE have detectable IgG. The absence of these antibodies strongly suggests another cause of the neurologic signs and symptoms.

The standard of care allows for the treatment of TE to be initiated on presumptive diagnosis when a typical neuroradiographic abnormality is noted on computed tomography (CT) or magnetic resonance imaging (MRI). MRI is more sensitive than CT in the demonstration of focal CNS lesions. The clinical diagnosis is a result of clinical and radiographic response to specific therapy

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

because patients may have similar symptoms resulting from lesions of other causes, such as CNS lymphoma, progressive multifocal leukoencephalopathy, brain abscess, and focal lesions caused by other organisms, including *Cryptococcus neoformans, Aspergillus* spp., *Mycobacterium tuberculosis,* and *Nocardia* spp. The practice of presumptive therapy for patients who have not been receiving effective prophylaxis for *Toxoplasma* with a characteristic finding on CT or MRI and positive serology for *Toxoplasma* is widely accepted. With the use of these criteria, the predictive value has been estimated at 80%. However, for patients such as intravenous drug abusers in whom other CNS processes are more prevalent, the predictive value of a positive serology for *Toxoplasma* is reduced, and the widespread use of prophylaxis may further reduce it. Toxoplasmic encephalitis is predominantly intra-axial, so significant meningeal involvement is uncommon. Examination of cerebrospinal fluid (CSF) is used to exclude other diseases. Detection of *T. gondii* DNA by polymerase chain reaction (PCR) in CSF has demonstrated high specificity but variable sensitivity in establishing the diagnosis of TE in AIDS patients with focal lesions.

The lungs are the second most common site of infection in AIDS patients and in recipients of bone marrow transplants. The clinical manifestations of toxoplasma pneumonia are nonspecific, similar to those seen with *Pneumocystis jirovecii* (*carinii*) pneumonia (PCP). Most patients have fever, a nonproductive cough, dyspnea, and occasionally hemoptysis. However, the onset of disease tends to be faster than with PCP. The chest roentgenogram typically reveals bilateral interstitial infiltrates, although multiple nodular infiltrates, single nodules, isolated cavitary disease, lobar infiltrates, pleural effusions, and hilar adenopathy may occur. Pneumothorax complicating toxoplasmic pneumonia has been reported, as well as acute respiratory distress syndrome (ARDS). The diagnosis relies on a high index of suspicion and the demonstration of *T. gondii* from bronchoalveolar lavage (BAL) fluid or biopsy specimens, given the nonspecific nature of both clinical and radiologic manifestations in most cases.

Ocular toxoplasmosis is the most common retinal infection in the United States and is the second most common retinal infection in patients with AIDS after cytomegalovirus (CMV) retinitis. Patients usually present with decreased visual acuity and, less often, eye pain. Ocular toxoplasmosis may be the sole manifestation of infection or may accompany TE or disseminated disease. At times, in the immunocompromised host, ocular toxoplasmosis is a harbinger of TE. A CT scan of the head should be obtained to assess presence of concomitant TE. Fundoscopic findings are consistent with a necrotizing chorioretinitis. The lesions, which may be single or multiple and bilateral and are usually nonhemorrhagic, are yellow-white areas of retinal necrosis with ill-defined fluffy borders. They occur at the posterior pole and may be associated with a moderate to severe inflammatory response in the vitreous and anterior chamber. These characteristics help in the differential diagnosis with CMV retinitis. Fluorescein angiography may also be helpful. Dye leakage tends to occur along the edge of the lesions in toxoplasmosis and to be more prominent in the center of lesions in CMV retinitis. Ocular toxoplasmosis should be suspected in the AIDS patient who is seropositive for *T. gondii* and has changes in visual acuity with accompanying fundoscopic changes. A prompt response to specific therapy should also be expected. Definitive diagnosis has been made by demonstrating the organism in retinal biopsy specimens or isolation of *T. gondii* from vitreal fluid or PCR.

THERAPY

Immunocompetent host

Most infections in immunocompetent hosts are asymptomatic and do not require therapy. Lymphadenopathy, the most common manifestation, is self-limited and usually resolves within 1 to 3 weeks. Treatment should be considered only if systemic symptoms are severe or long lasting or in the rare event of visceral involvement (encephalitis, myocarditis, pneumonitis). Acute infection as a result of laboratory accidents or transfusions may be severe and should be treated. The treatment regimen of choice consists of a combination of pyrimethamine (Daraprim) and sulfadiazine given for 2 to 4 weeks with folinic acid (leucovorin) (Table 199.1). In the event of pyrimethamine-induced hematologic toxicity, the dosage of folinic acid can be increased to 20 to 50 mg/day. For patients allergic to sulfa, clindamycin in combination with pyrimethamine and folinic acid has been used successfully (see Table 199.1).

For ocular toxoplasmosis, the drugs of choice are pyrimethamine and sulfadiazine or trisulfapyrimidine with folinic acid in the same dosages

Table 199.1 Drugs for treatment of toxoplasmic encephalitis and extraneural toxoplasmosis

Antimicrobial	Mode of action	Metabolism	Adverse effects	Recommended dosage (immunocompromised)	Recommended dosage (immunocompetent)
Pyrimethamine (Daraprim) oral	Inhibits folic acid synthesis	Readily absorbed by gut; hepatic metabolism, lipid soluble	Cytopenias, rash, GI intolerance	Acute: loading dose 200 mg then 50–75 mg daily; with oral folinic acid (leucovorin) 10–20 mg/d Maintenance: 25–50 mg/day with oral folinic acid 10–25 mg/d	Loading dose 200 mg daily for 2 d, then 50–75 mg daily for 2–4 wk; with oral folinic acid 10–20 mg/d
plus					
Sulfadiazine[a] oral	Inhibits folic acid synthesis; acts synergistically and sequentially with pyrimethamine	Readily absorbed by the gut; penetrates blood–brain barrier; some hepatic metabolism	GI intolerance, rash (Stevens–Johnson syndrome), cytopenias, nephrolithiasis, crystalluria, interstitial nephritis, encephalopathy	Acute: 1–1.5 g q6h Maintenance: 500–1000 mg/day QID	1–1.5 g q6h, 2–4 wk
or					
Clindamycin[a] oral and IV	Unknown; possibly inhibition of plastid and/or mitochondrial protein synthesis	Readily absorbed by gut; excellent tissue penetration	GI intolerance, rash, pseudomembranous colitis	Acute: 600 mg q6h (up to IV 1200 mg q6h) Maintenance: 300–450 mg PO q6–8h	300 mg q6h, 4 wk, repeat as needed

Abbreviation: GI = gastrointestinal.

[a] Used in combination with pyrimethamine.

Adapted from Mofenson *et al. MMWR Recomm Rep.* 2004;53(RR–14):1.

as described earlier. Therapy is given for 4 weeks and repeated as needed. Treatment is required to prevent relapse with the risk of progressive vision loss and other complications such as glaucoma. Adjunctive therapy with systemic corticosteroids (prednisone, 80 to 120 mg/day, or an equivalent) is indicated if the macula, optic nerve, or papillomacular bundle is involved.

Immunocompromised host

For TE, the combination of pyrimethamine, 200 mg loading dose in two divided doses followed by 50 to 75 mg/day orally, plus sulfadiazine, 4 to 6 g/day orally in four doses, remains the mainstay of treatment (see Table 199.1). Oral folinic acid is added to preclude the hematologic toxicities associated with antifolate agents. Acute therapy is recommended for at least 6 weeks. Longer treatment durations may be needed if there is extensive clinical and radiographic disease or the response is incomplete at 6 weeks. Patients who cannot tolerate sulfas can be given clindamycin in combination with pyrimethamine as described. Prophylactic use of anticonvulsants is not recommended. Corticosteroids should not be used routinely but are indicated if there is evidence of increased intracranial pressure. In one study, 70% of AIDS patients treated for TE had a quantifiable clinical improvement by day 7 of therapy. Conversely, patients not responding to empiric therapy had evidence of progressive disease within the first 10 days. Ninety percent of patients had improvement on neuroradiographic studies within 6 weeks of starting therapy.

In immunocompromised hosts, maintenance therapy (secondary prophylaxis) should be initiated. The regimen is usually the same as that used for primary treatment but at half dose. Maintenance therapy should be continued for the life of the patient or until the underlying immunosuppression has resolved. In patients with AIDS, secondary prophylaxis can be discontinued if they have sustained CD4 counts greater than 200 cells/mm^3 for longer than 6 months.

The same chemotherapeutic regimens are used for extraneural toxoplasmosis; however, there are limited data available on the optimal length and outcome of treatment. As a rule, ocular

Table 199.2 Alternative treatments of toxoplasmosis in immunocompromised patients

Antimicrobial	Mode of action	Metabolism	Adverse effects	Recommended dosages
Atovaquone (Mepron)[a] oral	Uncoupling electron biosynthesis; inhibition of de novo pyrimidine biosynthesis	Suspension has better bioavailability than old tablet formulation; improved absorption if taken with food, particularly fatty foods	Rash, elevated liver function tests	Acute: suspension 1500 mg q12h Maintenance: suspension 750 mg q6–12h
Azithromycin (Zithromax)[a] oral	Unknown; possibly inhibition of plastid and/or mitochondrial protein synthesis	Readily absorbed by gut; high intracellular levels	GI intolerance	Acute: 900–1200 mg/d Maintenance: same
Trimethoprim–sulfamethoxazole (TMP–SMX)[b] (Bactrim, Septra) oral or IV	Inhibits folic acid synthesis	Renal metabolism	Rash, Stevens–Johnson syndrome, bone marrow suppression, hepatotoxicity, increased serum creatinine	Acute: 5 mg/kg TMP and 25 mg/kg SMX IV or oral BID

Abbreviations: GI = gastrointestinal.

[a] Used in combination with pyrimethamine or sulfadiazine.

[b] Used in combination with pyrimethamine.

toxoplasmosis responds favorably to therapy, and treatment of pulmonary infection has been reported to be successful in 50% to 77% of patients.

Intravenous trimethoprim–sulfamethoxazole (TMP–SMX, Bactrim, Septra), at 5 mg/kg/day trimethoprim component, has been used when oral therapy is contraindicated. Although TMP–SMX is available for oral use, response rates have been lower than standard regimens. Recently, trials have shown higher initial response rates when the dose was increased (trimethoprim, 6.6 to 10 mg/kg body weight per day).

The drugs described thus far are active only against the tachyzoite form of *T. gondii*. Surviving tissue cysts can reinitiate TE and other manifestations of reactivated latent disease if treatment is discontinued. Therefore it is necessary to give long-term suppressive therapy. Pyrimethamine, 25 to 50 mg/day, and sulfadiazine, 2 to 4 g/day orally in four doses, with 10 mg/day of oral folinic acid is recommended because of the low relapse rate associated with this combination. Clindamycin is used in cases of sulfa allergy. Atovaquone monotherapy at 750 mg two to four times a day may be considered in patients who are unable to tolerate pyrimethamine; however, this regimen has a 1-year relapse rate of 26%.

Primary chemoprophylaxis is a very attractive therapeutic option for patients known to be at risk for toxoplasmosis (i.e., those with CD4 counts less than 100 cells/mm^3 and seropositive for anti-*T. gondii* antibodies). Retrospective data suggest that TMP–SMX, one double-strength tablet per day orally, is efficacious. Neither dapsone nor pyrimethamine, when used as a single agent, is consistently effective. However, the combination of pyrimethamine, 50 mg/week, plus dapsone, 50 mg/day, plus folinic acid has been a useful alternative. In patients with a sulfa allergy, desensitization is also an option. Primary prophylaxis can be safely discontinued when the patient has sustained immune reconstitution with a CD4 count greater than 200 cells/mm^3 for 3 months.

Other drug regimens that have proven useful as initial and maintenance therapy (Table 199.2) include atovaquone (Mepron). An AIDS Clinical Trials Group (ACTG) trial evaluating the efficacy of atovaquone-containing regimens (either in combination with pyrimethamine or sulfadiazine) showed encouraging results, with 77% response to therapy. As salvage therapy, atovaquone alone induced initial clinical response in 50% of study patients. The response to therapy with atovaquone has been directly correlated with serum drug levels achieved. The macrolide antibiotics azithromycin (Zithromax) and clarithromycin (Biaxin) in combination with pyrimethamine have limited utility as alternative agents.

Pregnancy

Women who acquire toxoplasmosis (primary infection) during pregnancy expose their fetuses to risk of infection. Infection of the fetus may result in stillbirth, spontaneous abortion, or birth of a symptomatic or an asymptomatic infant. Rarely, transmission has been reported in cases

Table 199.3 Drugs used in treatment of toxoplasmosis in pregnant women

In pregnant women infected during gestation	Medication	Dosage	Duration of therapy
First 18 wk of gestation or until term if fetus found not to be infected by amniocentesis at 18 wk	Spiramycin[a]	1 g every 8 h without food	Until fetal infection is documented or until it is excluded at 18 wk of gestation
If fetal infection confirmed, after wk 18 of gestation and in all women infected after wk 18	Pyrimethamine[b] plus	Loading dose: 50 mg each 12 h for 2 d; then beginning on day 3, 50 mg/d	Until term
	Sulfadiazine plus	Loading dose: 75 mg/kg; then beginning 50 mg/kg each 12 h (maximum 4 g/d) 10–20 mg daily	Until term
	Leucovorin (folinic acid)		During and for 1 wk after pyrimethamine therapy

[a] Spiramycin is not commercially available. Available only on request from the US Food and Drug Administration (telephone number: 301–443–5680), and then with approval by physician's request to Sanofi–Aventis (908–231–3365).

[b] Adjusted for megaloblastic anemia, granulocytopenia, or thrombocytopenia.

From Remington JS, McLeod R, Thulliez P, Desmonts G. Toxoplasmosis. In: Remington JS, Klein JO, Wilson CB, Baker CJ, eds. *Infectious Diseases of the Fetus and Newborn Infant*, 6th edn. Philadelphia, PA: Elsevier; 2006.

where the mother contracts acute toxoplasmosis 6 to 8 weeks before conception. Fetal infection is less common when the mother is treated during pregnancy. Early diagnosis, through serology, amniotic sampling for PCR, and fetal ultrasonography, is important in further management (antibiotics or therapeutic abortion).

Pyrimethamine plus a sulfonamide or spiramycin, a macrolide antibiotic available in western Europe, Mexico, and Canada and through the Food and Drug Administration of the United States, appears to decrease the incidence of congenital toxoplasmic infection when given to women who acquire *T. gondii* during pregnancy (Table 199.3). Pyrimethamine is teratogenic and should not be used until after the first trimester. There is no optimal medical therapy in the United States for treatment of women who become infected during the first trimester. However, sulfadiazine or trisulfapyrimidines should be used during the first trimester because sulfonamides alone have been shown to be effective in acute toxoplasmosis in animal models. If spiramycin can be obtained, pregnant women acutely infected in the first trimester may be treated until term with 30 to 50 mg/kg/day in three doses until fetal infection is confirmed or excluded. Treatment with spiramycin alone decreases the incidence of transmission but not the severity of established congenital infection. As spiramycin does not readily cross the placenta, treatment should be switched to pyrimethamine, sulfadiazine, and folinic acid in pregnant women with confirmed or a high possibility of fetal infection after the 18th week of gestation. If maternal or fetal infection is suspected or confirmed after the first trimester, pyrimethamine and sulfadiazine plus folinic acid should be used for treatment.

Pregnant women or women who are trying to become pregnant should be advised about risk factors for primary infection with toxoplasmosis. Education has been shown to be effective in decreasing the seroconversion rate during pregnancy. Women with cats should have someone else changing the litter box daily. They should avoid consuming undercooked meats, raw eggs, unpasteurized milk, or unfiltered water. All uncooked fruits and vegetables should be washed. Gloves should be used if they are working with soil, if they are preparing raw meat, or if they must change the cat litter box themselves. Proper hand hygiene should be practiced after working with soil, after handling the cat or the litter box, or after touching raw or undercooked meat.

200. Malaria

Jessica K. Fairley and Henry M. Wu

Malaria remains a life-threatening parasitic infection endemic throughout much of the world. It is estimated that in 2010 there were 216 million infections and 655 000 deaths due to malaria, with the majority of deaths among African children. In nonendemic countries, it is one of the most common causes of fever in returned travelers and recent immigrants, and several thousand people with malaria arrive in nonendemic countries yearly.

Malaria is a mosquito-borne protozoal infection caused by one of four human *Plasmodium* species (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*), or with the monkey parasite, *Plasmodium knowlesi*, which has been increasingly described in parts of Southeast Asia. Malaria endemic countries are shown in Figure 200.1. Given the risk of rapid progression to severe disease in nonimmune individuals, a high index of suspicion is critical when evaluating patients with febrile illness following travel to malarious areas, especially those endemic for *P. falciparum*. Proper treatment of malaria requires knowledge of the infecting species and where it was acquired, since drug resistance patterns vary geographically. Widespread chloroquine-resistant *P. falciparum* (CRPF) malaria and emergence of resistance to other drugs have complicated treatment and prophylaxis.

CLINICAL ASPECTS

Fever in a patient who has recently traveled to an area endemic for malaria should be considered a medical emergency. The minimum incubation period is generally considered to be 7 days after inoculation, and of greatest concern is the patient who has traveled to a *P. falciparum* endemic area within 2 months of presentation, since an incubation period of 2 to 4 weeks is typical for falciparum malaria. Presentation several months to 1 year after departing an endemic region is also possible, particularly when infected with *P. vivax* or *P. ovale*, since infection with these species can result in a dormant liver stage. Patients with falciparum malaria can also present months after exposure, as the use of prophylaxis or presence of semi-immunity can modify or delay the onset. For these reasons, febrile patients who have traveled to a malarious region in the preceding year should be ruled out for malaria, regardless of prophylaxis history.

Malaria transmission occurs when a malaria-infected female *Anopheles* mosquito inoculates sporozoites into a human host. Initially, infected persons are asymptomatic as the sporozoites enter the bloodstream and travel to the liver where maturation occurs in hepatocytes. Malaria symptoms begin when merozoite forms are released into the bloodstream, and the erythrocytic stage begins. In this stage, merozoites infect erythrocytes and replicate within them, resulting in rupture and further merozoite release. Symptom severity typically depends on the percentage of erythrocytes infected and the presence or absence of partial immunity due to previous infection.

Initial symptoms are nonspecific and include fever, chills, malaise, anorexia, headaches, and myalgias. Cough, abdominal pain, and diarrhea may also be present. The illness may resemble numerous other febrile syndromes including enteric fever, dengue fever, influenza, meningitis, and septicemia, so a high index of suspicion for malaria is critical, even when an alternate diagnosis appears more likely. Although regular periodicity of fever is classically described, this is unlikely early in the disease course and may not be seen at all, particularly with falciparum malaria.

Severe falciparum malaria is a multiorgan system disease. Infected erythrocytes adhere to vascular endothelium cells, resulting in sequestration, circulatory obstruction, and inflammation in the affected organ. Complications include

severe anemia, jaundice, thrombocytopenia, hypoglycemia, pulmonary edema, acute respiratory distress syndrome (ARDS), renal failure, and disseminated intravascular coagulation (DIC). Seizures, impaired consciousness, and coma may result from hypoglycemia or suggest the presence of cerebral malaria. Even with treatment, the case-fatality rate of severe malaria is 15% to 20%. Lactic acidosis suggests a worse prognosis. Nonimmune pregnant woman are at higher risk for severe disease, as well as preterm birth and fetal loss. Among travel-associated cases in nonendemic countries, patients over 65 years old have the worst outcomes. Though *P. vivax* typically causes uncomplicated malaria, severe *P. vivax* malaria can occur. However, since severe disease is most associated with falciparum malaria and mixed infection with multiple species is possible, severe disease in a patient diagnosed with non-falciparum malaria should raise the possibility of coexisting falciparum malaria.

P. vivax and *P. ovale* infections can also result in a dormant hypnozoite liver stage which requires special consideration for treatment and prophylaxis. Patients carrying hypnozoites are asymptomatic until the infection reactivates, resulting in a relapsed infection.

DIAGNOSIS

Prompt and accurate diagnosis is critical in malaria management. The diagnostic gold standard is examination of Giemsa-stained thick and thin blood smears. Thick smears are highly sensitive and can detect parasites in patients with low parasitemia levels that might be missed in thin smears. However, thin smears are best for speciation, quantification of parasites (i.e., percent of erythrocytes parasitized), and assessment of treatment response. If the initial blood smears are negative, they should be repeated at 12- to 24-hour intervals for a total of three sets before considering the disease ruled out. When expertise to prepare or examine thick smears is not immediately available, thin blood smears alone are better than none at all, since a negative thin smear suggests a high parasitemia infection is unlikely. Wright's stain, which is typically used in clinical laboratories for peripheral blood smears, is not optimal for blood parasites; however, it can be helpful when Giemsa staining is unavailable.

A number of rapid diagnostic tests (RDTs) are available for malaria diagnosis when blood smears are not readily available. These tests rely on the detection of *Plasmodium* spp. antigens, including histidine-rich protein 2 (HRP2) and parasite lactate dehydrogenase. These tests can be highly sensitive and specific for falciparum malaria. However, test performance can vary widely among different kits and false results can occur if instructions on use and storage are not strictly followed. Nonetheless, RDTs can be important in situations where microscopy is not feasible or timely.

THERAPY

The increasing prevalence of drug-resistant plasmodia has complicated malaria treatment. In addition to widespread CRPF, mefloquine-resistant *P. falciparum* is endemic in several Southeast Asian countries, and strains of *P. vivax* resistant to drugs including chloroquine and primaquine have emerged. In contrast, drug resistance has not been described in *P. ovale* or *P. malariae*. When species identification is uncertain in a patient with malaria, clinicians should treat for the worst-case scenario, i.e., infection caused by CRPF. Malaria acquired while taking prophylaxis should not be treated with the same medication used for prophylaxis. Recommended drug regimens for treatment in the United States are listed in Table 200.1. Since effective malaria therapy requires consideration of the infecting species and local resistance patterns, clinicians are strongly advised to review current recommendations and to seek diagnostic assistance when needed. Suspected or confirmed malaria should always be treated with the assistance of an infectious diseases or tropical medicine specialist when available. Updated country guides and detailed US treatment recommendations are available from the Centers for Disease Control and Prevention (CDC), either online (www.cdc.gov/malaria/index.html) or by phone through the CDC Malaria Hotline (1–770–488–7788 or 1–855–856–4713 toll free, weekdays 9AM–5PM; or 1–770–488–7100 for emergency consultation after hours).

[1] Malaria acquired while taking prophylaxis should not be treated with the same medication used for prophylaxis.

[2] Infection acquired in Southeast Asia should be treated for 7 days with quinine/quinidine, and infections acquired in Africa and South America should be treated with 3 days of quinine/quinidine.

[3] Doxycycline and tetracycline are not indicated for children <8 years old.

[4] Treatment with mefloquine is not recommended for infections acquired in Southeast Asia due to *P. falciparum* resistance in this region. Due to high rates of neuropsychiatric side effects at treatment doses, mefloquine is only recommended when other options (i.e., atovaquone/progruanil, artemether–lumefantrine, quinine-based regimens) cannot be used.

[5] G6PD deficiency and pregnancy must be ruled out prior to primaquine use to eradicate hypnozoites in *P. vivax* and *P. ovale* infections. Expert consultation recommended in patients with G6PD deficiency or pregnant patients.

[6] *P. vivax* acquired in Papua New Guinea or Indonesia should be considered as potentially chloroquine-resistant and treated with alternative regimens. See www.cdc.gov/malaria/diagnosis_treatment/index.html for recommendations.

Adapted from: Centers for Disease Control and Prevention, 2013.

hydroxychloroquine should be used to treat *P. falciparum* from these areas, as well as *P. malariae* and *P. knowlesi* infections from any part of the world.

Uncomplicated chloroquine-resistant *P. falciparum* malaria

With the exception of the regions mentioned above, CRPF is widespread. Artemisinin-based combination therapies (ACTs) are rapidly becoming the treatment of choice for CRPF. Artemisinin and its derivatives are well tolerated and lead to a rapid reduction in parasitemia and fever. Since monotherapy is associated with a high rate of recrudescence, the addition of a second agent is necessary. ACTs currently recommended by the World Health Organization (WHO) include artemether–lumefantrine, artesunate–amodiaquine, artesunate plus mefloquine, artesunate plus sulfadoxine–pyrimethamine, and dihydroartemisinin–piperaquine. Recently, artemether–lumefantrine has been approved in the United States for the oral treatment of uncomplicated falciparum malaria. Atovaquone–proguanil is another recommended and well-tolerated oral regimen for uncomplicated falciparum malaria. These regimens are effective against multidrug-resistant falciparum malaria acquired in Southeast Asia.

When artemether–lumefantrine and atovaquone–proguanil are not available or are contraindicated, oral quinine sulfate in combination with tetracycline, doxycycline, or clindamycin is an effective regimen, though longer and less well tolerated. Clindamycin is usually reserved for pregnant women and for young children (those

less than 8 years old) in whom tetracycline derivatives are generally avoided. Patients taking quinine typically experience cinchonism, the reversible symptom complex that includes tinnitus, dizziness, headache, nausea, visual disturbances, and hearing loss. These side effects usually do not necessitate drug change. If oral medication is not tolerated, parenteral treatment is necessary (see parenteral regimens below for severe malaria).

Mefloquine is also effective therapy for uncomplicated CRPF malaria, but it is not recommended for patients who might have multidrug-resistant infections acquired in Southeast Asia, particularly along the Thai–Myanmar (Burma) or Thai–Cambodian borders. Furthermore, concern for significant side effects generally restrict its use and make it an alternative regimen for uncomplicated malaria. Severe neuropsychiatric adverse reactions (psychosis, convulsions) are more likely to occur when the drug is used at treatment doses compared to prophylaxis dosing. Due to the QTc prolonging effects of mefloquine, an alternative regimen should be used in patients with a history of arrhythmia.

The use of pyrimethamine–sulfadoxine (Fansidar) is no longer recommended due to widespread resistance to this regimen. Though halofantrine is widely used in malaria endemic areas, the CDC recommends against its use due to the risk of potentially fatal cardiac adverse events.

Plasmodium vivax malaria

The erythrocytic stage of *P. vivax* malaria is effectively treated with chloroquine or hydroxychloroquine. Eradication of hepatic hypnozoites requires treatment with primaquine. Primaquine is a potent oxidizing agent; therefore, glucose-6-phosphate dehydrogenase (G6PD) deficiency must be ruled out before primaquine therapy is initiated to avoid severe hemolysis.

Chloroquine-resistant *P. vivax* malaria was first described on the island of New Guinea in 1989 with subsequent spread across Indonesia. Since then, there are sporadic reports of declining chloroquine efficacy elsewhere in Southeast Asia, Africa, and the Amazon Basin of South America. Malaria caused by chloroquine-resistant *P. vivax* should be suspected when the illness recurs within 28 days after a patient has received standard therapy with chloroquine and primaquine. Due to the risk of chloroquine resistance, *P. vivax* malaria originating from Indonesia or Papua New Guinea should be treated with alternative regimens (Table 200.1). Notably, a recent Cochrane review concluded that some ACTs are as effective as chloroquine in treating the blood stage *P. vivax* infection, suggesting a potential strategy for simplifying empiric treatment for all forms of uncomplicated malaria where *P. falciparum* and *P. vivax* coexist.

Though somewhat controversial, primaquine-resistant *P. vivax* malaria has been reported from the island of New Guinea, other parts of Southeast Asia, Somalia, and Colombia. When a relapse of *P. vivax* occurs more than 28 days after treatment with chloroquine and primaquine, primaquine resistance should be considered.

Plasmodium ovale malaria

Malaria caused by *P. ovale*, found mostly in Africa, is managed in the same way as chloroquine-sensitive *P. vivax*. No drug-resistant strains of *P. ovale* have been documented.

Severe *P. falciparum* malaria

Even with appropriate treatment, the mortality rate of severe falciparum malaria ranges from 15% to 20%. Management comprises four main areas: clinical assessment, specific antimalarial treatment, adjunctive therapy, and supportive care. Severe falciparum malaria is typically defined by the presence of parasitemia of $\geq$5% or signs of major organ failure. Signs of major organ failure may include impaired consciousness/coma, severe anemia, renal failure, ARDS, hypotension, DIC, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, and repeated seizures.

Patients with severe malaria require parenteral therapy with quinidine (or parenteral quinine, if available). Continuous electrocardiographic monitoring is essential due to the high rates of cardiac arrhythmias with treatment. Intravenous artesunate has also been found to be a safe and effective treatment, and it is a WHO preferred treatment for severe falciparum malaria. In the United States, artesunate is not Food and Drug Administration (FDA)-approved; however, in cases where IV quinidine is either contraindicated or unavailable, artesunate is available from the CDC through an investigational new drug (IND) protocol. Clinicians needing artesunate should contact the CDC Malaria Hotline (see above for contact information). Both quinidine and

artesunate regimens require the addition of a second drug as outlined in Table 200.1.

Supportive care is critical for the effective management of severe malaria. Blood glucose must be monitored closely, as hypoglycemia is a common complication, especially in pregnant women and children, and can contribute to impaired consciousness and seizure activity. Furthermore, both quinine and quinidine cause insulin to be released from the pancreas. Fluid balance should be corrected judiciously with the aim of avoiding fluid overload that increases the risk of ARDS. Exchange transfusion has historically been used as an adjunctive treatment for severe malaria, but a 2013 CDC analysis did not show a survival benefit and it is no longer recommended. Other important supportive measures include mechanical ventilation for ARDS and hemodialysis for renal failure. Ruling out coexisting infections such as meningitis and septicemia is important, and empiric antimicrobials might be indicated.

PREVENTION

Malaria prevention in travelers involves both prophylaxis and protective measures against mosquito bites. The primary goal of prophylaxis is to prevent *P. falciparum* infection in nonimmune travelers because almost all fatal cases are associated with illness caused by this species. Careful review of itineraries is important when advising travelers to assess whether they will enter malaria endemic areas and the presence of any drug resistance. Risk can vary widely within a country. For example, when travel to Thailand is limited to the malaria-free cities of Bangkok and Phuket, prophylaxis is not needed, whereas travel to many rural areas in Thailand warrants prophylaxis against multidrug-resistant *P. falciparum*. Travel timing should also be considered, as some regimens require starting 1 to 2 weeks prior to departure, and the number of tablets prescribed will be determined by the duration of travel. Other considerations include medical contraindications to specific regimens, drug–drug interactions between prophylaxis drugs and the traveler's usual medications, and client preference. Client preference is often based on side-effect profile, convenience of the regimen, and cost. A general algorithm for determining an appropriate prophylactic regimen is shown in Figure 200.2. Since malaria distribution and resistance patterns can change, clinicians are strongly advised to review current country-specific recommendations, such as those provided by the CDC (www.cdc.gov/malaria/travelers) when advising travelers.

The various malaria prophylactic agents have different schedules, though all require starting prior to arrival in the malarious area and continuation after departure for a specified period (Table 200.2). Weekly chloroquine remains an excellent option for travel to the limited endemic areas without CRPF, though atovaquone-proguanil, doxycycline, and mefloquine are also options. For most areas with CRPF, prophylaxis with atovaquone–proguanil, doxycycline, and mefloquine are recommended. An exception exists for travel to areas in Southeast Asia with multidrug-resistant strains where atovaquone–proguanil and doxycycline are the only options.

Mefloquine prophylaxis has a weekly schedule and should be started 2 weeks prior to entering malaria-risk areas. It is generally well tolerated by most travelers, though it can cause sleep disturbance, dizziness, and abnormal dreams. Mefloquine has been associated with rare but severe neurologic or neuropsychiatric side effects, including permanent vestibular toxicity, seizures, psychosis, anxiety, and depression. Its use is contraindicated in travelers with a history of active or recent major psychiatric or seizure disorder, and travelers prescribed mefloquine should be informed of potential adverse effects. Because the majority of adverse reactions to mefloquine occur with the first three doses, if possible it is prudent to commence the drug 4 weeks prior to departure to ascertain drug tolerance. Atovaquone–proguanil and doxycycline have daily schedules and can be started 1 to 2 days prior to arriving to the malaria-risk area. Both drugs are usually well tolerated, but doxycycline can cause photosensitivity and gastrointestinal side effects such as nausea and esophagitis. Travelers taking doxycycline should be advised to take it with food and sufficient fluids, and it should not be taken at bedtime. Mefloquine and doxycycline need to be continued for 4 weeks after departing from the malaria-risk area, while atovaquone–proguanil needs only to be continued for 7 days.

Prolonged exposure to malaria in areas intensely endemic for *P. vivax* or *P. ovale* (e.g., Central America, northwest Africa, South Asia, Oceania) warrants terminal prophylaxis with primaquine to eradicate hypnozoites. As previously noted, G6PD deficiency should be ruled out before prescribing this drug, and it is contraindicated during pregnancy. Primaquine also has a potential role in

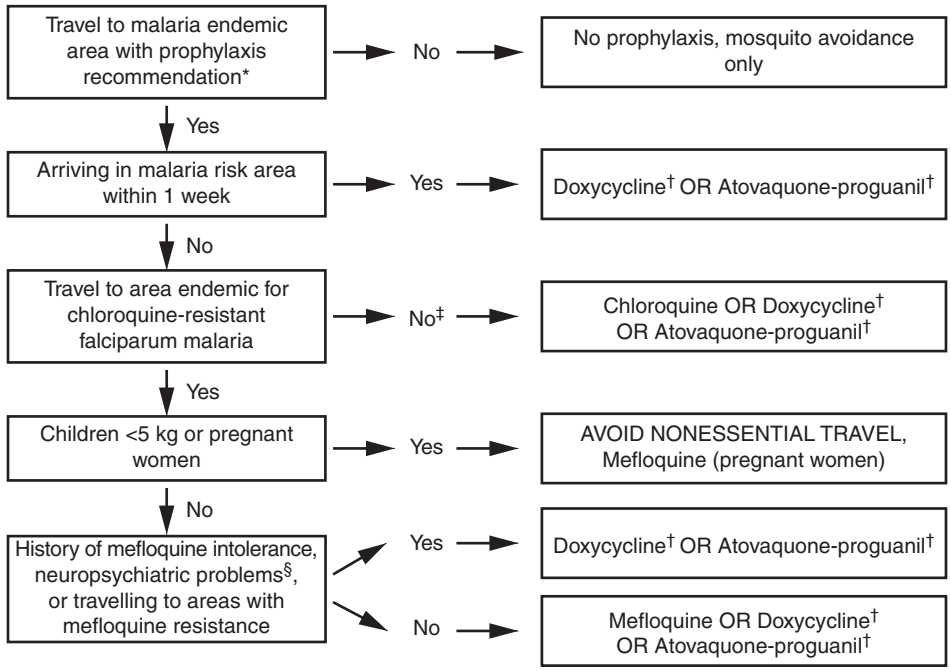

Figure 200.2 Algorithm for the prophylaxis of malaria. See Table 200.2 for dosages.
* Country-specific recommendations available at: www.cdc.gov/malaria/travelers.
† Contraindicated or not recommended in pregnancy.
‡ If traveling for short durations to an area with primary *P. vivax* malaria, primaquine primary prophylaxis is an option if glucose-6-phosphate deficiency and pregnancy are ruled out.
§ Seizures, psychosis, schizophrenia, generalized anxiety disorder, active or recent depression, other major psychiatric disorders.

primary prophylaxis for short-term travelers to areas with primarily *P. vivax* malaria.

Prophylaxis options for pregnant women are limited to mefloquine in areas with CRPF and chloroquine in areas without CRPF. Unfortunately, there are no recommended prophylactic regimens for pregnant women traveling to areas with multidrug-resistant *P. falciparum* in Southeast Asia. Long-term travelers (such as missionaries or overseas workers) and immigrants visiting their countries of origin pose additional challenges. These travelers often have itineraries and accommodations that are higher risk for malaria than those of typical short-term travelers. Long-term travelers often adhere poorly to prophylaxis and mosquito-bite avoidance recommendations. Immigrants visiting friends and relatives in their country of origin often do not seek pre-travel advice and are often unaware that any malaria semi-immunity wanes quickly. Substandard or counterfeit drugs are also a common problem in developing countries, so travelers should be strongly cautioned against obtaining prophylaxis medications locally.

Because no prophylaxis regimen is 100% effective, all travelers to malarious regions need to be meticulous about personal protection measures. Furthermore, malarious areas are often endemic for other mosquito-transmitted infections, such as dengue fever. Insect repellents containing 30% to 50% of diethyltoluamide (DEET) are very effective. The CDC, American Academy of Pediatrics, and US Environmental Protection Agency have indicated that 30% DEET is safe for infants as young as 2 months of age. Other effective compounds used in repellents include picaridin, oil of lemon eucalyptus (OLE), PMD, and IR3535. Permethrin-impregnated protective clothing (long sleeves, pants) add further protection. Travelers should always follow product instructions carefully so they are used safely and are reapplied at appropriate intervals. Since *Anopheles* mosquitoes typically bite between dusk

Table 200.2 Malaria chemoprophylaxis regimens

Drug	Adult dose	Pediatric dose	Adverse effects
Chloroquine phosphate	300 mg base (=500 mg salt) PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	5 mg base/kg (=8.3 mg salt/kg) PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	Bitter taste, headache, pruritus, rash, blurry vision, reversible corneal opacity, partial alopecia. Rare: retinopathy, blood dyscrasias, nail discoloration, nerve deafness, myopathy. May exacerbate psoriasis
Hydroxychloroquine	310 mg base (=400 mg salt) PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	5 mg base/kg (=6.5 mg salt/kg), maximum 310 mg base, PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	As for chloroquine
Atovaquone–proguanil	250 mg atovaquone and 100 mg proguanil (1 adult tablet) PO daily, starting 1–2 d before entering malarious area and continue for 7 d after departing risk area	Weight-based daily dose starting 1–2 d before entering malarious area and continue for 7 d after departing risk area. Pediatric tablet contains 62.5 atovaquone and 25 mg proguanil: 5–8 kg: ½ ped tab PO daily >8–10 kg: ¾ ped tab PO daily >10–20 kg: 1 ped tab PO daily >20–30 kg: 2 ped tab PO daily >30–40 kg: 3 ped tab PO daily >40 kg: see adult dosing	Nausea, abdominal pain, headache. May transiently increase transaminases. Rare: rash. Take with food. Do not use if creatinine clearance ≤30 mL/min. Not recommended for pregnant women, breastfeeding women, or children <5 kg
Doxycycline	100 mg PO daily, starting 1–2 d before entering malarious area and continue for 4 wk after departing risk area	≥8 years old: 2.2 mg/kg PO daily (maximum dose 100 mg/d), starting 1–2 d before entering malarious area and continue for 4 wk after departing risk area	Esophageal irritation, gastrointestinal upset, photosensitivity, candida vaginitis. Stains teeth of children aged ≤8 yr and fetuses. Contraindicated in pregnancy
Mefloquine	One 228 mg base tablet (=250 mg salt) PO weekly, starting ≥2 wk before entering malarious area and continue for 4 wk after departing risk area	Weight-based daily dose starting ≥2 wk before entering malarious area and continue for 4 wk after departing risk area: ≤9 kg: 4.6 mg base/kg (=5 mg salt/kg) PO weekly >9–19 kg: ¼ tablet PO weekly >19–30 kg: ½ tablet PO weekly >30–45 kg: ¾ tablet PO weekly >45 kg: 1 tablet PO weekly One tablet contains 228 mg base (=250 mg salt)	Dizziness, nausea, diarrhea, headache, nightmares, altered dreams, insomnia, mood changes. Rare: seizure, psychosis, permanent vestibular toxicity. Do not use if history of seizures, psychosis, schizophrenia, generalized anxiety disorder, active or recent depression, other major psychiatric disorders, or cardiac conduction abnormality present
Primaquine			
Terminal prophylaxis	30 mg base (52.6 mg salt) PO daily for 14 d	0.5 mg base/kg (0.8 mg salt/kg) PO daily for 14 d	G6PD deficiency should be ruled out prior to use to prevent hemolysis. Contraindicated in pregnancy and breastfeeding women. Should be taken with food to prevent gastrointestinal upset
Primary prophylaxis (for short-duration travel to areas with primarily *P. vivax*)	30 mg base daily, starting 1–2 d before entering malarious area and continue for 7 d after departing risk area	0.5 mg base/kg (0.8 mg salt/kg) PO daily, starting 1–2 d before entering malarious area and continue for 7 d after departing risk area	

and dawn, sleeping under permethrin-impregnated bed netting or in screened-in or air-conditioned rooms is important.

Because malaria prophylaxis recommendations often vary according to different authorities, travelers should be cautioned about potentially conflicting advice from fellow travelers and overseas healthcare providers. Also, travelers should be advised to seek medical attention immediately in the event of high fever during travel, as well as

those that occur up to a year after travel. Acutely ill travelers should seek the best medical care available and follow local treatment recommendations. However, since malaria is often overdiagnosed in developing countries, travelers should be strongly cautioned against discontinuing their prophylaxis regimen if they are diagnosed with malaria.

201. Human babesiosis

Tempe K. Chen, Choukri Ben Mamoun, and Peter J. Krause

Babesiosis is an emerging zoonotic disease caused by intraerythrocytic protozoa and transmitted by ticks. The first well-documented case of human *Babesia* infection was reported in 1957 in a splenectomized resident of Yugoslavia, who died after an acute illness marked by anemia, fever, hemoglobinuria, and renal failure. Intraerythrocytic parasites were noted and tentatively identified as *Babesia bovis*. Since then, other *Babesia* species have been found to cause disease in humans: *Babesia microti*, *Babesia duncani*, *Babesia duncani*-type, and *Babesia divergens*-like in North America; *B. divergens*, *B. microti*, and *Babesia venatorum* in Europe; and *B. microti*-like and KO-1 in Asia. The clustering of cases of human *B. microti* infection in the United States contrasts with the sporadic occurrence of the disease in Europe, Africa, and Asia. Rarely, babesiosis may be transmitted through blood transfusion or transplacentally.

EPIDEMIOLOGY

More than 90 species in the genus *Babesia* infect a wide variety of wild and domestic animals. Humans are an uncommon and terminal host for *Babesia* species, which depend on other species for their development and transmission. The most common cause for human babesiosis is *B. imicroti*, a babesia of rodents. The primary reservoir for *B. microti* in eastern North America is the white-footed mouse (*Peromyscus leucopus*). As many as two-thirds of *P. leucopus* have been found to be parasitemic in endemic areas. *Babesia* species are transmitted by hard-bodied (ixodid) ticks. The primary vector in eastern North America is *Ixodes scapularis* (also known as *Ixodes dammini*), which is the same tick that transmits *Borrelia burgdorferi*, the etiologic agent of Lyme disease, and *Anaplasma phagocytophilum*, the agent of human granulocytic anaplasmosis. Thus, simultaneous human infection with two or more of these pathogens may occur.

Each of the three active stages in the life cycle of *I. scapularis* (larva, nymph, and adult) takes a blood meal from a vertebrate host to mature to the next stage (Figure 201.1). The *Babesia* species ingested by one tick stage are transmitted to the next stage. The tick transmission cycle begins in late summer when newly hatched larvae ingest the parasite during a blood meal from an infected rodent and maintain the parasite to the nymphal stage. Nymphs transmit the *Babesia* species to rodents in late spring and summer of the following year. Larvae, nymphs, and adults can feed on humans, but the nymph is the primary vector (Figure 201.2). All active tick stages also feed on the white-tailed deer (*Odocoileus virginianus*), which is an important host for the tick but is not a reservoir for *B. microti*. An increase in the deer population over the past few decades is thought to be a major factor in the spread of *I. scapularis* and in the resulting increase in human babesia cases.

Beginning in the 1980s, human babesiosis has been described with increasing frequency at sites in the northeastern and northern midwestern United States. Recent studies suggest that the endemic range continues to expand. In certain sites during years of high transmission, babesiosis may constitute a significant public health burden. For example, in one study of a highly endemic area in Rhode Island, approximately 9% of the population had serologic evidence of previous *B. microti* infection compared with 11% of previous Lyme disease. Most human cases of babesiosis occur in the summer and in areas where the vector tick, rodents, and deer are in close proximity to humans. Rarely, babesiosis is acquired through transfusion of blood products, including whole blood, packed red cells, cryopreserved red cells, and platelets. Transplacental/perinatal transmission of babesiosis has also been described.

PATHOGENESIS

Our understanding of the pathogenesis of human babesiosis is incomplete and is primarily based on studies done in animals. Cytoadherence of infected erythrocytes to vascular epithelium may diminish access of host immune factors to babesia. Cytoadherence may prevent transit of infected erythrocytes through the spleen where they would be destroyed, thus allowing babesia to complete their life cycle and invade other erythrocytes. Excessive cytoadherence may lead to erythrocyte sequestration and obstruction of microvasculature with subsequent tissue anoxia, as has been demonstrated in cattle infected by *B. bovis*. Similarly, production of host proinflammatory cytokines such as tumor necrosis factor (TNF) and interleukin (IL)-1 help to destroy intracellular babesia; however, excessive cytokine production associated with moderate to severe disease probably accounts for the majority of

Figure 201.2 *Ixodes scapularis* (also known as *Ixodes dammini*) ticks showing larval, nymphal, and adult stages.

clinical manifestations and complications of the disease. T cells, B cells, macrophages, neutrophils, antibody, and complement also are important in clearing parasitemia and may contribute to disease pathogenesis.

CLINICAL MANIFESTATIONS

The clinical severity of babesiosis ranges from subclinical infection to fulminating disease resulting in death. In clinically apparent cases, symptoms of babesiosis begin after an incubation period of 1 to 9 weeks from the beginning of tick feeding or 6 weeks to 6 months after transfusion. In most cases, there is a gradual onset of malaise, anorexia, and fatigue followed by intermittent temperatures as high as 40°C (104°F) and one or more of the following symptoms: chills, sweats, myalgia, arthralgia, nausea, and vomiting. Less commonly noted are emotional lability, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough. The findings on physical examination generally are minimal, often consisting only of fever. Mild splenomegaly, hepatomegaly, or both are noted occasionally. Slight pharyngeal erythema, jaundice, retinopathy with splinter hemorrhages, and retinal infarcts also have been reported. Rash is seldom noted, although ecchymoses and petechiae have been described in severe disease.

Symptoms usually persist for a few weeks to several months, with prolonged recovery of up to 18 months in severe cases. Parasitemia may continue even after a person feels well and may persist for >2 years with subsequent relapse of illness. Although prolonged symptomatic disease unresponsive to antimicrobial therapy or death may occur in immunocompromised hosts, complete recovery with or without therapy is the rule.

Patients at increased risk for more severe babesial disease include those with malignancy, concomitant human immunodeficiency virus (HIV) infection, asplenia, age greater than 50 years, immunosuppressive medication regimens, or infection with *B. divergens* or *B. duncani*. Concurrent babesiosis and Lyme disease infection occurs in about 3% to 15% of patients experiencing Lyme disease in parts of southern New England and results in more severe acute Lyme disease illness. Moderate to severe babesiosis may occur in children, but infection often results in mild disease and is generally less debilitating than in adults. Several cases of neonatal babesiosis have been described, usually following transfusion with infected blood, and sometimes resulting in severe illness. Symptoms and signs include lethargy, tachypnea, pallor, poor feeding, splenomegaly, hepatomegaly, jaundice, and generalized macular rash.

COMPLICATIONS

A severe form of babesiosis has been noted in some patients, consisting of fulminant illness lasting about a week and ending in death or a prolonged convalescence. Although more common in immunocompromised hosts or those experiencing *B. divergens* or *B. duncani* infection, severe babesiosis can occur in otherwise healthy individuals who are infected with *B. microti*. In a retrospective study of 136 patients with *B. microti* infection from Long Island, New York, 7 patients (5%) died. The patients with fatal illness ranged in age from 60 to 82 years, and only one was known to be immunocompromised. Signs and symptoms in severe cases include high fever, severe hemolytic anemia, hemoglobinemia and hemoglobinuria, jaundice, ecchymoses, petechiae, congestive heart failure, pulmonary edema, renal failure, adult respiratory distress syndrome, and coma. Patients with asplenia, malignancy, and/or HIV infection may experience a chronic form of babesiosis that is unresponsive to multiple courses of standard antibabesial therapy.

DIAGNOSIS

Babesiosis should be suspected in any patient with unexplained febrile illness who has recently lived or traveled in endemic regions during the months of May through September, with or without a history of tick bite. There is often no

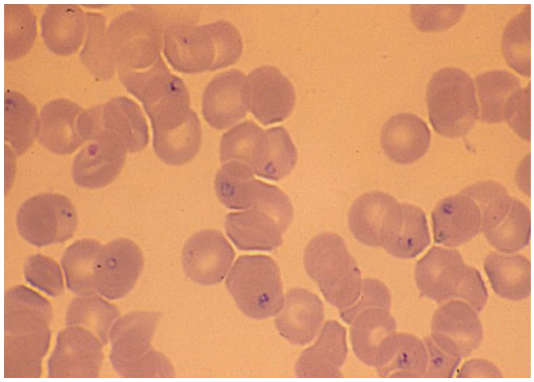

Figure 201.3 Ring forms of *Babesia microti* in human blood film (1000×).

recollection of a tick bite, because the unengorged *I. scapularis* nymph is difficult to discern with the naked eye (~2 mm in length). Babesiosis also should be suspected in any patient with unexplained febrile illness who has had a blood transfusion within the previous 6 months.

Laboratory findings reflect the invasion and subsequent lysis of erythrocytes by the parasite and the immune response to infection. They include moderate to severe hemolytic anemia, an elevated reticulocyte count, thrombocytopenia, an elevated erythrocyte sedimentation rate, elevated serum bilirubin and liver enzyme concentrations, elevated serum blood urea nitrogen and creatinine concentrations, and proteinuria. The leukocyte count is normal to slightly decreased, with a "left shift." Atypical lymphocytes also may be noted on manual differential blood smear examination.

Specific diagnosis of babesiosis is made by microscopic demonstration of the organism using Giemsa-stained thin blood smears. Giemsa-stained *Babesia* parasites appear as round, oval, or pear-shaped microorganisms with a blue cytoplasm and a red chromatin membrane (Figure 201.3). Multiple blood fields should be examined because only a few erythrocytes are infected in the early stage of the illness when most people seek medical attention. Fewer than 1% of erythrocytes may be parasitized initially and may escape detection. Maximum erythrocyte infection is approximately 10% in normal hosts but up to 85% in people who are immunocompromised. Thick blood smears may be examined, but the organisms appear as simple chromatin dots that may be mistaken for stain precipitate or iron inclusion bodies. Accordingly, only someone with extensive experience in interpreting thick smears should perform this method. The ring form is most common and is very similar to the intraerythrocytic ring forms of *Plasmodium falciparum*. Although the presence of tetrad forms ("Maltese cross") is said to be diagnostic, such elements are rarely encountered. Similarly, the absence of hemozoin (malarial pigment) is often considered to be generally diagnostic for the small blood stage parasites (piroplasms), but early ring stages of the plasmodia also lack pigment. Diagnosis is thus made by a combination of criteria and, in severe cases, includes the presence of high parasitemia, erythrocytes infected by multiple parasites, and basket-shaped merozoites that are often extracellular.

Physicians can further confirm babesial infection by use of polymerase chain reaction (PCR), serologic testing, and small animal inoculation. Both immunoglobulin G and immunoglobulin M antibodies can be detected using an immunofluorescent assay (IFA). The babesia IFA is sensitive and specific and may quickly confirm a diagnosis of babesiosis when parasites are rare or not detectable. During the acute phase of the illness, titers usually exceed 1:1024 but decline to 1:64 or less within 8 to 12 months. Thus, a babesial IFA titer of 1:1024 or greater usually signifies active or recent infection. A serologic cutoff point of 1:64 generally is considered to be diagnostic. Although cross-reactions occur to different *Babesia* species and *Plasmodium* species with the IFA test, these titers are almost always low (1:16 or less). The PCR is a sensitive and specific test for detection of babesia DNA. Proper technique must be used to prevent false-positive results. Where laboratory expertise exists, blood from the patient can be injected by the intravenous (IV) or intraperitoneal route into small laboratory animals such as hamsters or gerbils. If present in the patient, *B. microti* usually appears in the blood of the inoculated animal within 2 to 4 weeks. The diagnosis of babesiosis is suspect in symptomatic patients whose serum contains antibody to babesia, but whose blood lacks identifiable babesial parasites on smear or babesia DNA by PCR.

For *B. divergens* babesiosis, specific antibodies do not become detectable until at least 1 week after onset of illness. Because this infection is rapidly fulminating, serologic diagnosis is not practical in the diagnosis of acute infection, but serologic conversion serves as an aid in retrospective diagnosis during convalescence. The high parasitemias that are present are easily detected by blood smear in the acute phase of

Table 201.1 Treatment of babesiosis

Medication	Dose of antibabesia drug (all drugs given for 7 to 10 days or longer)		Comment
	Adults	**Children**	
Clindamycin plus	300–600 mg IV q6h or 600 mg PO q8h	7–10 mg/kg/dose IV or PO q6–8h (maximum 600 mg/dose)	This combination is the treatment of choice for severe babesiosis. Exchange transfusion or partial exchange transfusion should be considered in such patients
Quinine	650 mg PO q6–8h	8 mg/kg/dose PO q8h (maximum 650 mg/dose)	
Atovaquone plus	750 mg PO q12h	20 mg/kg/dose PO q12h (maximum 750 mg/dose)	This combination is the treatment of choice for mild to moderate babesiosis. A dose of 600–1000 mg/q24h may be used for immunocompromised adult patients
Azithromycin	500–1000 mg PO on d 1, then 250 mg PO/q24h	10 mg/kg as a single dose PO on d 1 (maximum 500 mg/dose), then 5 mg/kg PO q24h (maximum 250 mg/dose)	

infection. Infection by *B. duncani* may readily be detected by blood smear or by demonstrating specific antibody by IFA. This species may be cultivated in vitro. Unlike the IFA for *B. microti*, a higher cutoff value (>1:160) is required to impart specificity, for unknown reasons. In humans and in rodent models, tetrad forms are frequently seen in blood smears, but otherwise this agent is difficult to distinguish from *B. microti*.

Coinfection with the agents of Lyme disease (*B. burgdorferi*), human granulocytic anaplasmosis (*A. phagocytophilum*), or both may occur in patients experiencing babesiosis in geographic areas where these pathogens are endemic. Coinfection should be considered in patients who present with rash or more severe initial symptoms than are commonly observed with babesiosis alone, or who do not respond to standard therapy.

TREATMENT

Early efforts to treat patients with babesiosis were unsuccessful, including use of the antimalarial drug chloroquine. The combination of clindamycin and quinine was the first effective antimicrobial therapy and remains the treatment of choice for severe babesiosis. Clindamycin is given to adults as 300 to 600 mg IV every 6 hours or 600 mg orally every 8 hours and to children in a 7 to 10 mg/kg/dose, up to a maximum dose of 600 mg, given IV or orally every 6 to 8 hours. Quinine is given as 650 mg orally every 6 to 8 hours in adults and 8 mg/kg/dose up to a maximum dose of 650 mg, given orally every 6 hours, in children. The clindamycin and quinine combination generally is administered for 7 to 10 days. This combination frequently produces untoward reactions, such as tinnitus, QT prolongation, allergic reaction, vertigo, and gastrointestinal upset. Treatment failures have been reported in patients with splenectomy, HIV-infected patients, and those receiving concurrent corticosteroid therapy (Table 201.1).

The successful use of atovaquone and azithromycin for treatment of malaria and for treating babesiosis in a hamster model of infection suggested that this combination might also be useful against human babesiosis. In the first prospective, randomized trial of antibabesial therapy in humans, the combination of atovaquone and azithromycin was compared with that of clindamycin and quinine for treatment of adults with *B. microti* infection. The atovaquone and azithromycin combination was found to be as effective in clearing parasitemia and resolving symptoms as the clindamycin and quinine combination. Both drug combinations were given by mouth for 7 days. After 3 months, there was no evidence of piroplasms or amplifiable *B. microti* DNA in either group. Significantly fewer adverse effects were associated with the atovaquone and azithromycin combination. Three-fourths of patients receiving clindamycin and quinine experienced adverse drug reactions, and one-third were forced to decrease the dose or to discontinue the medication. Adverse effects of therapy included hearing loss, tinnitus, syncope, hypotension, and gastrointestinal symptoms (anorexia, vomiting, and diarrhea). In contrast, only 18% in the azithromycin and atovaquone group experienced symptoms consistent with adverse drug reaction, and none required a

decrease in dosage or discontinuation of medication. The conclusions of this study were (1) antibabesial therapy based on the atovaquone and azithromycin drug combination generally is superior to that based on clindamycin and quinine, mainly because the atovaquone and azithromycin regimen is well tolerated, whereas the clindamycin and quinine regimen frequently is not, and (2) physicians should consider the use of atovaquone and azithromycin in adult patients experiencing mild or moderate babesial symptoms and in others who cannot tolerate clindamycin and quinine. The currently recommended dose for atovaquone is 750 mg orally every 12 hours in adults or 20 mg/kg/dose up to a maximum dose of 750 mg, given orally every 12 hours, in children, whereas that for azithromycin is 500 to 1000 mg on day 1 and then 250 mg/day thereafter in adults or 10 mg/kg/day as a single dose (up to a maximum dose of 500 mg) given orally on day 1, and 5 mg/kg/dose (up to a maximum dose of 250 mg) given orally once per day thereafter in children. Higher doses of 600 to 1000 mg/day may be used for immunocompromised patients experiencing babesiosis.

The combination of pentamidine (240 mg IV/day) and trimethoprim–sulfamethoxazole (3 g/day) was found be moderately effective in clearing parasitemia and symptoms due to *B. divergens*. Potential adverse reactions to pentamidine that include pain at the site of injection, formation of sterile abscess, hyperglycemia or hypoglycemia, and nephrotoxicity limit the use of this combination.

Clindamycin (administered intravenously) and quinine should be given to patients experiencing babesiosis who are more severely ill with high parasitemia (>10%), significant hemolysis, or renal or pulmonary compromise. In addition, exchange transfusion should be considered in such patients. Partial exchange transfusion (packed red blood cells) or complete exchange (whole blood exchange) as well as plasmapheresis are rapid and reliable methods of decreasing parasitemia by removing parasite-infected red blood cells from the circulation. They also help remove vasoactive elements such as cytokines and thromboplastic substances that may contribute to renal failure and disseminated intravascular coagulation. Due to the risks associated with multiple blood exposures, these techniques should not be considered as routine therapy but only used for those severely ill with babesiosis, such as patients with a high parasitemia and coma, hypotension, congestive heart failure, pulmonary edema, or renal failure. In combination with clindamycin and quinine, exchange transfusion is the treatment of choice for all cases of *B. divergens* babesiosis.

Patients with babesiosis should be monitored closely during therapy. In most cases, improvement will occur within 1 or 2 days after antiprotozoal therapy is begun. Symptoms generally resolve within 1 or 2 months after clindamycin and quinine or atovaquone and azithromycin therapy is completed. In severely ill patients (especially those with asplenia or HIV), the hematocrit and percentage of erythrocytes parasitized should be monitored daily or every other day until the patient has improved and the parasitemia has decreased to less than 5%. Blood smears should be examined every 4 hours following the first dose of clindamycin and quinine, and alternative therapy should be considered if parasitemia does not appreciably decline within 24 hours. Some patients may have persistence of low-grade parasitemia for months following antibiotic therapy. Because low-grade parasitemia may be difficult to detect on thin blood smear, the more sensitive PCR for amplifying parasite DNA should also be considered. Physicians should consider retreatment of patients with antibabesial therapy if patients show evidence of parasitemia in their blood for more than 3 months after initial therapy, especially if parasitemia is increasing.

Physicians also should consider the possibility of coinfection with Lyme disease, human granulocytic anaplasmosis, or both in patients who experience especially severe or persistent symptoms despite appropriate antibabesial therapy. Such patients may benefit from the addition of doxycycline therapy because neither clindamycin and quinine nor atovaquone and azithromycin have been shown to be effective for the treatment of Lyme disease or human granulocytic anaplasmosis.

PREVENTION

Prevention of babesiosis can be accomplished by avoiding areas from May through September where ticks, deer, and mice are known to thrive. It is especially important for those at increased risk in endemic areas, such as asplenic individuals, to avoid tall grass and brush where ticks may abound. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide (DEET), dimethyl phthalate, or permethrin (Permanone) is recommended for those who travel in the foliage of endemic areas. DEET has been shown to be more effective than other repellents against ticks,

but the risk of adverse effects is greater. Topically applied DEET is absorbed into the systemic circulation and as much as 10% to 15% of each dose can be found in the urine. Dermatologic effects such as bullous eruptions and urticaria have been documented. Systemic effects such as toxic encephalopathy, anaphylaxis, and grand mal seizures have been noted with higher DEET concentrations. Finally, DEET ingestion may be fatal to both children and adults. Thus, although DEET can help to prevent tick bites and is generally well tolerated when applied to the skin properly, care must be taken with repeated use of high concentration products.

A search for ticks on people and pets should be carried out and the ticks removed using tweezers to grasp the mouthparts without squeezing the body of the tick. Prophylactic antibiotics after a tick bite to prevent babesiosis are not indicated. The effects of reduction of the tick, mouse, or deer populations in endemic areas on the incidence of human babesiosis have not been evaluated. Blood donors with a history of babesiosis are excluded from donating blood to prevent transfusion-related cases. Effective vaccines have been developed to prevent *B. divergens* and *B. bovis* infections in cattle, but no vaccines are currently available for the prevention of human babesiosis.

202. Trypanosomiases and leishmaniases

Anastácio de Queiroz Sousa, Selma M. B. Jeronimo, and Richard D. Pearson

American trypanosomiasis (Chagas disease), human African trypanosomiasis (HAT, sleeping sickness), and leishmaniasis are caused by related protozoa of the family Trypanosomatidae, order Kinetoplastida (see Table 202.1). They have a unique mitochondrial structure, the kinetoplast, are transmitted in nature by insect vectors, and exist in multiple morphologic forms in their human hosts and insect vectors. They are important causes of morbidity and mortality in endemic areas of the world: Chagas disease in South and Central America, sleeping sickness in sub-Saharan Africa, and leishmaniasis in scattered areas on every continent except Antarctica. Although uncommon in industrial countries in North America and Europe, these diseases have been the source of increased attention in recent years. Infection with *Trypanosoma cruzi*, the cause of Chagas disease, is well documented among Latin American immigrants to North America and Europe and poses a risk to them, children of infected mothers, and to recipients of contaminated blood or transplanted organs. Cutaneous leishmaniasis is seen among tourists returning from endemic areas in Latin America and the Middle East as well as in military personnel who have served in Iraq, Afghanistan, and other endemic areas. Imported cases of visceral leishmaniasis in travelers or immigrants from the Indian subcontinent, East Africa, South America or southern Europe, some in association with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), occur, but are rare. Canine visceral leishmaniasis has been reported in the United States among foxhounds and other dogs, but to date, humans have not been infected.

Despite several important recent advances, the treatment of Chagas disease, African trypanosomiasis, and leishmaniasis leaves much to be desired. Many of the drugs (Table 202.2) used for them are associated with frequent and potentially severe untoward effects, some require parenteral administration, and many must be administered over prolonged periods of time. The only drugs approved by the US Food and Drug Administration (FDA) for these diseases are liposomal amphotericin B for visceral leishmaniasis and miltefosine for visceral and cutaneous leishmaniasis. Other drugs listed in the table are investigational or used off-label. Several can be obtained from the Centers for Disease Control and Prevention (CDC) Drug Service (Atlanta, Georgia) along with detailed information about administration

Table 202.1 Diseases caused by protozoa of the family Trypanosomatidae

Disease	Causative agent	Geographic distribution	Vector	Reservoir
American trypanosomiasis (Chagas disease)	*Trypanosoma cruzi*	Americas	Triatomine (Reduviid) bugs; occasionally infected juices or foods	Multiple species of animals
African trypanosomiasis (sleeping sickness)	*Trypanosoma brucei gambiense* *Trypanosoma brucei rhodesiense*	West and Central Africa East Africa	Tsetse flies (*Glossina* species)	Humans, domestic animals (minor role) Large game animals
Leishmaniasis (visceral, cutaneous, mucosal)	*Leishmania* species	Worldwide	Sand flies (*Phlebotomus* species and *Lutzomyia* species)	Rodents, canines (dogs, foxes), or humans

Table 202.2 Treatment of trypanosomiasis and leishmaniasis

Drug of choice	Adult dosage	Pediatric dosage
American trypanosomiasis/Chagas disease (*Trypanosoma cruzi*)		
Nifurtimox[a,b]	8–10 mg/kg/d in 3–4 doses × 90 d	1–10 yr : 15–20 mg/kg/d in 3–4 doses × 90 d
Or		11–16 yr: 12.5–15 mg/kg/d in 3–4 doses × 90 d
		≥17 yr: same as adult dose × 90 d
Benznidazole[a,b]	5–7 mg/kg/d in 2 divided doses × 60 d	<12 yr: 5–7.5 mg/kg/d in 2 doses × 60 d
		≥12 yr: 5–7 mg/kg/d in 2 doses × 60 d
East African sleeping sickness (*Trypanosoma brucei rhodesiense*)		
Hemolymphatic stage		
Suramin[a,b]	100 mg (test dose) IV, then 1 g IV on days 1,3,5,14, and 21	100 mg (test dose), then 20 mg/kg (max 1 g) on days 1,3,5,14, and 21
Late stage with central nervous system involvement		
Melarsoprol[a,b,c]	2–3–6 mg/kg/d × 3 d; after 7 d	2–3.6 mg/kg/d × 3 d; after 7 d
	3.6 mg/kg/d × 3 d; repeat again after 7 d	3.6 mg/kg/d × 3 d; repeat again after 7 d
West African sleeping sickness (*Trypanosoma brucei gambiense*)		
Hemolymphatic stage		
Pentamidine[d,e]	4 mg/kg/d IM or IV × 7–10 d	4 mg/kg/d IM or IV × 7–10 d
Alternative: Suramin[a]	100 mg (test dose) IV, then 1 g IV on days 1,3,5,14, and 21	100 mg (test dose) IV, then 20 mg/kg/d (max 1 g) on days 1,3,5,14, and 21
Late stage with central nervous system involvement		
Eflornithine[a,f]	400 mg/kg/d IV in 4 doses × 14 d	400 mg/kg/d IV in 4 doses × 14 d
Leishmaniasis (*Leishmania* species)		
Visceral[g]		
Liposomal amphotericin B[h,i]	3 mg/kg IV (d 1–5, 14, and 21)	3 mg/kg IV (d 1–5, 14, and 21)
Alternatives		
Sodium stibogluconate[a]	20 mg sb/kg/d IV or IM × 28 d[j]	20 mg sb/kg/d IV or IM × 28 d[j]
Or		
Meglumine antimonate[a]	20 mg sb/kg/d IV or IM × 28 d[j]	20 mg sb/kg/d IV or IM × 28 d[j]
Or		
Miltefosine[k]	50 mg PO TID × 28 d	≥12 yr and 30–44 kg: 50 mg PO BID × 28 d
		≥45 kg: same as adult dose × 28 d
Or		
Amphotericin B[d]	0.5–1 mg/kg IV daily or every second day for a total dose of 15–20 mg/kg	1 mg/kg IV daily or every second day for a total dose of 15–20 mg/kg
Cutaneous[l]		
Local therapy:	Cryotherapy (with liquid nitrogen)	
	Thermotherapy (use of localized current field radiofrequency heat)	
	Intralesional administration of Sb^V (not covered by CDC's protocol for Pentostam)	
	Application of paromomycin (as an ointment containing 15% paromomycin; not commercially available in the United States)[m]	
Systemic therapy:	Application of imiquimod	
Sodium stibogluconate[a]	20 mg sb/kg/d IV or IM × 20 d[h]	20 mg sb/kg/d IV or IM × 20 d[j]
Or		
Meglumine antimonate[a]	20 mg sb/kg/d IV or IM × 20 d[j]	20 mg sb/kg/d IV or IM × 20 d[j]
Or		
Liposomal amphotericin	3 mg/kg/d IV for 6–10 doses	3 mg/kg/d IV for 6–10 doses
Or		
Amphotericin B deoxycholate[d]	0.5–1.0 mg/kg daily or every other day for a total dose of approx. 20 mg/kg	0.5–1.0 mg/kg daily; or every other day for a total dose of approx. 20 mg/kg
Or		
Miltefosine[n]	50 mg PO TID × 28 d	≥12 yr and 30–44 kg: 50 mg PO BID × 28 d
		≥45 kg: same as adult dose × 28 d
Or		
Fluconazole[d,o]	8 mg/kg/d PO for 4–6 wk	8 mg/kg/d PO for 4–6 wk

Miltefosine[q]	50 mg PO TID × 28 d	≥12 yr and 30–44 kg: 50 mg PO BID × 28 d ≥45 kg: same as adult dose × 28 d

[a] Based on the recommendations of the Centers for Disease Control and Prevention, 2013 and the Medical Letter for Drugs and Therapeutics, 2008

[b] Available under an Investigational New Drug (IND) protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; 404–639–3670 (evenings, weekends, or holidays: 404–639–2888).

[c] In frail patients, begin with as little as 18 mg and increase the dose progressively. Pretreatment with suramin has been advocated for debilitated patients. Corticosteroids have been used to prevent arsenical encephalopathy. Up to 20% of patients with *T. b. gambiense* fail to respond to melarsoprol.

[d] An approved drug, but considered investigational for this condition by the FDA.

[e] For treatment of *T. b. gambiense*, pentamidine and suramin have equal efficacy, but pentamidine is better tolerated.

[f] Eflornithine is highly effective in *T. b. gambiense* but not against *T. b. rhodesiense* infections. It is available in limited supply only from the World Health Organization (WHO) and the CDC.

[g] Visceral infection is most commonly caused by *Leishmania donovani* and *Leishmania infantum* (previously known as *Leishmania chagasi* in Latin America). Treatment may vary based on symptoms, host immune status, species, and resistance pattern in the area where infection was acquired.

[h] Several lipid formulations of amphotericin B have been used for treatment of visceral leishmaniasis. Largely based on clinical trials in patients infected with *L. infantum*, the FDA approved liposomal amphotericin B (AmBisome) for treatment of visceral leishmaniasis. Amphotericin B lipid complex (Abelcet) and amphotericin B cholesteryl sulfate (Amphotec) are considered investigational.

[i] The FDA-approved dosage regimen for immunocompromised patients (e.g., HIV infected) is 4 mg/kg/d (d 1–5) and 4 mg/kg/d on d 10, 17, 24, 31, and 38. The relapse rate is high; maintenance therapy may be indicated, but there is no consensus as to dosage or duration.

[j] May be repeated or continued; a longer duration or higher dose may be needed for some patients treated with liposomal amphotericin.

[k] Gastrointestinal adverse effects are common, and the drug is contraindicated in pregnancy and breastfeeding. Resistance has been reported. Miltefosine is approved for *L. donovani* infection acquired in the Indian subcontinent.

[l] Cutaneous infection is most commonly due to the Old World species *Leishmania major*, *Leishmania tropica* and *Leishmania aethiopica* and New World species *Leishmania mexicana*, *Leishmania amazonensis, Leishmania (Viannia) panamensis*, *Leishmania (Viannia) braziliensis*, and others. The choice of treatment varies based on the location and characteristics of the lesion(s), host immune status, infecting *Leishmania* species, and area of the world where infection was acquired. If lesions are small, few in number, cosmetically inconsequential, and not caused by *Leishmania* species associated with mucosal disease, they can be followed expectantly if there is evidence of self-healing or the lesions may be treated locally. An oral or parenteral systemic option is used for the rest. The final choice depends on the infecting species or geographic location of acquisition and the relative toxicity of the treatment modality.

[m] Topical paromomycin should be used only in geographic regions where cutaneous leishmaniasis species have low potential for mucosal spread.

[n] Oral miltefosine is approved for the treatment of cutaneous and mucosal leishmaniasis due to *L. (V.) panamensis*, *L. (V.) braziliensis*, and *L. (V.) guyanensis*. See note k for adverse effects.

[o] Several azoles have been used with variable effects. Early reports suggested that fluconazole 200 mg/d for 6 weeks was effective in American military personnel with *L. major*, but failures have been reported with that dose with lesions caused by other *Leishmania* species. Fluconazole at higher doses, 8 mg/kg for 4–6 weeks, has been reported to be effective in the treatment of *L. (V.) braziliensis* in an observational study in Brazil.

[p] American mucosal leishmaniasis is most often due to *L. (V.) braziliensis*, but may be seen in persons infected with *L. (V.) panamensis, L. (V.) guyanensis* and other species. The selection among treatment options is based on symptoms, host immune status, infecting *Leishmania* species, and site where the infection was acquired.

Abbreviations: CDC = Centers for Disease Control and prevention; FDA = Food and Drug Administration; IV = intravenously; IM = intramuscularly; sb = pentavalent antimony.

and side effects and administered under an Investigational New Drug (IND) protocol. The high cost of some of these medications and the lack of availability of others are important determinants in therapeutic decisions in impoverished endemic areas. Hopefully, more effective, less toxic approaches to chemotherapy and/or protective vaccines will become available in the future.

AMERICAN TRYPANOSOMIASIS (CHAGAS DISEASE)

Chagas disease, which is caused by *T. cruzi*, is transmitted by triatomine (reduviid or kissing) bugs that reside in buildings in rural areas of Latin America and occasionally in contaminated juices or foods. *Trypanosoma cruzi* infects a large number of animal species as well as humans.

There are an estimated 8 to 10 million persons infected in the world. The parasite develops in the intestine of the triatomine bug and is passed in feces when it takes a blood meal. The bite causes itching, and parasites may enter the skin through the imperceptible bite site when the person scratches. They may also be transferred to the conjunctiva where they can enter in the absence of a lesion.

The invasion that follows can elicit a local inflammatory nodule or chagoma. When parasites invade through the conjunctiva, unilateral, painless, periorbital edema (Romaña's sign) may develop. After a period of local multiplication, trypomastigotes disseminate through the bloodstream, causing acute Chagas disease with fever, other constitutional symptoms, carditis, and, rarely, meningoencephalitis. Death can result, but the acute phase is often mild or asymptomatic. Symptoms usually resolve over 4 to 8 weeks as host immune responses develop. The indeterminate phase of infection follows in which persons are entirely asymptomatic but continue to harbor the parasite. Eventually, 20% to 30% of infected individuals progress to chronic Chagas with cardiac, esophageal, or large intestinal involvement. Progressive, disseminated Chagas disease with carditis and/or brain abscesses has been reported in a limited number of persons with AIDS, following transplants or associated with other immunocompromising conditions. *Trypanosoma cruzi* is present in the bloodstream and organs of persons throughout the period of infection. Transmission can occur through transfusion of contaminated blood or transplantation of contaminated organs. This has posed ongoing problems in endemic areas in Latin America and is of increasing concern in North America and Europe related to immigration. Congenital transmission and accidental laboratory infections are well documented.

The diagnosis of acute Chagas disease is frequently made by identifying the parasite in blood or body tissues (Figure 202.1). Several serologic assays have been developed to detect antitrypanosomal antibodies in persons with indeterminate phase or chronic Chagas disease. The tests tend to be highly sensitive, but not always specific. They are routinely used in blood banks in endemic areas. A screening test for anti-*T. cruzi* immunoglobulin G antibodies approved by the FDA is used to detect infected blood and organ donors in the United States. In addition to protecting potential recipients, screening has brought to medical attention a number of infected immigrants now living in the United States and Canada.

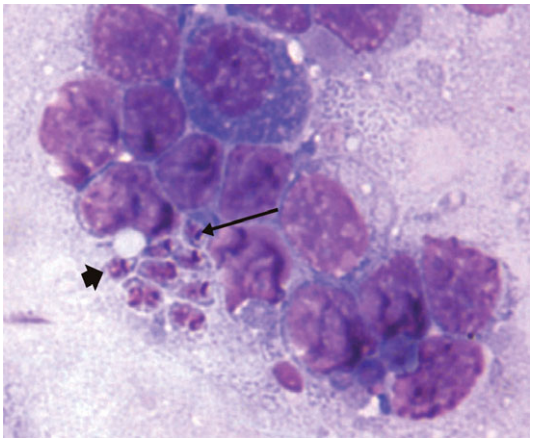

Figure 202.1 An imprint from a lymph node biopsy of a child with acute Chagas disease showing amastigotes (*arrowhead*), with large kinetoplast (*arrow*). Culture in LIT from the node and from whole blood grew *Trypanosoma cruzi*.

The drugs of choice are benznidazole or nifurtimox. Both are available under an IND protocol from the CDC Drug Service. Benznidazole has been the mainstay of therapy in Latin American countries. Nifurtimox has been used in the United States. Untoward effects are common with both drugs and may necessitate premature discontinuation of therapy.

Nifurtimox (Bayer 2502, Lampit; Bayer) is typically given for 90 days (see Table 202.2 for dosage). The drug is better tolerated in children and adolescents than in adults; higher doses per kilogram of body weight are used in younger patients. Neurologic and gastrointestinal side effects are common. They include sleep disturbances, restlessness, tremor, memory loss, paresthesias, weakness, polyneuritis, and, rarely, seizures, as well as anorexia, nausea, vomiting, abdominal pain, and weight loss. Other, rare side effects include fever, pulmonary infiltrates, and effusions.

Benznidazole (Rochagan, Roche) is usually administered for a period of 60 days. Higher doses are used in children. Side effects are frequent and include gastrointestinal disturbances, psychiatric manifestations, dose-dependent neuropathy, and cutaneous hypersensitivity reactions. On rare occasions hepatitis or neutropenia develops.

Treatment is indicated for all cases of acute or reactivated Chagas disease and for indeterminate or congenital infection up to age 18 years. Treatment is strongly recommended for adults up to

50 years old with chronic infection who do not already have advanced cardiomyopathy. For those older than 50 years with chronic *T. cruzi* infection, the decision to treat is individualized, weighing the potential benefits and risks, based on the patient's age, clinical status, and preference.

Once the cardiac, esophageal, or large intestinal manifestations of chronic Chagas disease develop, neither drug appears to alter the outcome. Supportive therapy includes cardiotropic drugs for congestive heart failure and arrhythmias, pacemaker placement for heart block, and palliative endoscopic or surgical procedures for esophageal and intestinal megadisease. Nifurtimox has been used to treat disseminated infection in persons who have undergone cardiac transplantation for chagasic cardiomyopathy in the United States.

HUMAN AFRICAN TRYPANOSOMIASIS (HAT, SLEEPING SICKNESS)

Human African trypanosomiasis is caused by *Trypanosoma brucei gambiense*, which is endemic in West and Central Africa, and *Trypanosoma brucei rhodesiense* in East Africa. Uganda is the only country where both exist. The African trypanosomes are transmitted by tsetse flies, which are found only in sub-Saharan Africa. Humans are the primary reservoir of *T. b. gambiense*, whereas *T. b. rhodesiense* is found primarily in large game animals. There are an estimated 50 000 to 70 000 new cases yearly although reporting is poor. Transplacental transmission and transmission through contaminated blood or transplanted organs can occur but are uncommon. *Trypanosoma b. gambiense* (West African trypanosomiasis) accounts for approximately 90% of all cases of HAT worldwide, but it is rarely encountered in the United States and in industrialized areas. There is on average approximately one case of HAT per year, with most being due to *T. b. rhodesiense* (East African trypanosomiasis) in the United States.

An indurated chancre may develop at the site of parasite inoculation. It is more likely to come with *T. b. rhodesiense* than *T. b. gambiense* infection. The early (hemolymphatic) stage of *T. b. gambiense* is characterized by recurrent bouts of fever, rash, headaches, edema of the face, myalgias, arthralgias, other constitutional symptoms, and lymphadenopathy. Swollen posterior cervical nodes are known as Winterbottom's sign. Trypanosomes may be seen in the blood or aspirates of lymph nodes. After a period of several weeks to months they invade the central nervous system, producing meningoencephalitis. Symptoms and findings include headaches, which may be severe, loss of concentration, personality changes, memory loss, seizures, difficulty walking, increased sleeping, and eventually obtundation, coma, wasting, and death.

In *T. b. rhodesiense* infection, systemic symptoms develop a few days to several weeks after the tsetse fly bites. A chancre may be present. Fever, headache, severe fatigue, irritability, lymphadenopathy, myalgias, and arthralgias follow. Death can occur within several weeks or months if treatment is not initiated. The courses may be indistinguishable, but *T. b. rhodesiense* infection is usually more acute and severe, and lymphadenopathy is not as prominent as it is with *T. b. gambiense* infection.

All cases of human African sleeping sickness must be treated. Given the complexity of the treatment regimens and toxicity of the drugs, consultation with experts at the CDC or elsewhere is recommended. Eflornithine, which has been called the "resurrection drug," is highly effective for hemolymphatic and central nervous system disease caused by *T. b. gambiense* and, when available, is the treatment of choice for West African sleeping sickness. Unfortunately, it is expensive and logistically difficult to administer in rural, endemic areas of Africa, and supplies are very limited. A 14-day course administered intravenously (IV) is recommended for late stage disease (Table 202.2). The combination of eflornithine and nifurtimox appears promising for central nervous system disease with *T. b. gambiense* based on recent studies. Eflornithine is not active against *T. b. rhodesiense*.

When eflornithine is not available, persons with hemolymphatic disease due to *T. b. gambiense* can be treated with either pentamidine isethionate, a 7-day course administered parenterally, or suramin. Pentamidine and suramin are of comparable efficacy for *T. b. gambiense*, but pentamidine is less toxic.

Toxicity is frequent with suramin and includes gastrointestinal disturbances such as nausea and vomiting; neurologic side effects such as photophobia, hyperesthesias, and peripheral neuropathy; and urticaria and pruritus. Administration of the drug is occasionally associated with shock, renal toxicity, optic atrophy, or blood dyscrasias. A test dose of suramin is given IV prior to the administration of treatment doses.

Pentamidine isethionate is administered daily, intramuscularly (IM) or IV. If infused too rapidly, IV pentamidine can produce hypotension and shock. Gastrointestinal disturbances, pain at the injection site when the drug is given IM, liver enzyme abnormalities, and nephrotoxicity are other side effects. Some patients develop life-threatening hypoglycemia due to pancreatic beta cell injury and insulin release; insulin-dependent diabetes may follow. Rare side effects include acute pancreatitis, hyperkalemia, anaphylaxis, and ventricular arrhythmias.

Melarsoprol (*Arsobal*, Rhone-Poulenc Rorer) is used to treat persons with central nervous system involvement with *T. b. gambiense* in sites where eflornithine is not available, and it is the only effective drug for persons with central nervous system disease due to *T. b. rhodesiense*. Melarsoprol is administered IV (see Table 202.2). Untoward effects are common with melarsoprol. In addition to encephalopathy, which occurs in as many as 18% of recipients and is fatal in 3% to 10%, treatment is frequently associated with nausea, vomiting, abdominal pain, peripheral neuropathy, hypertension, allergic reactions, and, rarely, shock. Administration of prednisolone, 1 to 2 mg/kg/day, appears to reduce the severity of arsenical encephalopathy and the risk of death by approximately half. A number of dosage regimens have been studied. Reduced doses of melarsoprol have been used in cachectic patients. Low-dose melarsoprol plus nifurtimox (see Chagas disease above) has also been used.

LEISHMANIASIS (CUTANEOUS, MUCOSAL, AND VISCERAL)

Leishmaniasis refers to the spectrum of disease caused by more than 20 *Leishmania* spp. that infect humans and other vertebrate hosts. The major clinical syndromes include cutaneous, mucosal, and visceral leishmaniasis, but a variety of other presentations, including post-kala-azar dermal leishmaniasis, diffuse cutaneous leishmaniasis, disseminated cutaneous leishmaniasis, and viscerotropic leishmaniasis, have been described. *Leishmania* spp. are transmitted by sand flies in nature. In many areas of the world, leishmaniasis is a zoonosis with dogs, other canines, or rodents serving as reservoirs, and humans becoming infected when they venture into endemic habitats. An outbreak of canine visceral leishmaniasis has been reported in the United States among foxhounds and some other dogs. Infection seems to occur by dog-to-dog or in utero transmission. There have been no human cases. In some sites such as India, humans are the only reservoir of visceral leishmaniasis. The manifestations of disease depend on interactions between the infecting *Leishmania* sp. and the genetically determined cell-mediated immune responses of its human host (Figures 202.2–202.9).

In persons with cutaneous leishmaniasis, parasites multiply in macrophages at the site of inoculation in the skin and in draining lymph nodes. The morphology of the resulting lesion is variable. Often, a nodule develops, expands, and then ulcerates over a course of weeks. Lesions may be single or multiple. Some have a "pizza-like" appearance with a raised, erythematous, outer border, a central area of red granulation tissue, and a yellowish or brown overlying crust. Others are "volcano-like" or flat and plaque-like. Lesions can persist for months to years but eventually heal leaving a burn-like scar as evidence of disease. In mucosal leishmaniasis due to *Leishmania (Viannia) braziliensis* and related species in Latin America, mucosal lesions of the nose, oral pharynx, and occasionally other sites develop months to years after the initial skin lesion has healed.

The majority of persons infected with *Leishmania donovani*, *Leishmania infantum* (formerly known as *Leishmania chagasi* in Latin America), or other *Leishmania* species associated with visceral leishmaniasis are asymptomatic, despite parasitemia in some instances, and have spontaneously resolving infections. In the subset of persons who develop progressive visceral leishmaniasis, known as kala-azar, parasites disseminate throughout the reticuloendothelial system. They are found within macrophages in the liver, spleen, bone marrow, and occasionally other organs. Patients typically present with massive splenomegaly, hepatomegaly, fever, weight loss, constitutional symptoms, and hypergammaglobulinemia. Visceral leishmaniasis has emerged in Spain, southern France, Italy, and elsewhere in southern Europe as well as Brazil as an opportunistic infection in persons with AIDS and others with compromised cell-mediated immunity. Persons with concurrent visceral leishmaniasis and AIDS may present in the classical manner, but atypical presentations are common. Splenomegaly may be absent, and gastrointestinal and pleuropulmonary involvement are often seen.

The diagnosis of cutaneous or visceral leishmaniasis is suggested by a history of exposure in

Figure 202.2 (**A and B**) Brazilian child with advanced visceral leishmaniasis and massive hepatosplenomegaly.

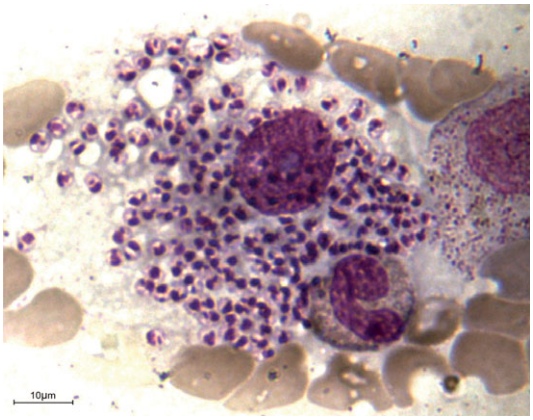

Figure 202.3 A macrophage with more than 100 amastigotes from a bone marrow aspirate of an AIDS patient with kala-azar.

an endemic region and the clinical findings. It is confirmed by identifying leishmania amastigotes, by smear, culture, or molecular tests for DNA, in blood, bone marrow, splenic aspirates, lymph node, or other tissue from patients with visceral leishmaniasis or in biopsies of skin lesions from those with cutaneous leishmaniasis. Antileishmanial antibodies are present at high titer in persons with visceral leishmaniasis but may be absent in persons with AIDS. Several assays are available; an enzyme-linked immunosorbent assay using a recombinant 39-kDa kinesin-like antigen is the most sensitive and specific for visceral leishmaniasis. Serology is not diagnostic in cutaneous leishmaniasis, as antileishmanial antibodies are variably present and at low titer. The leishmanin (Montenegro) skin test (Figure 202.10) is not

available in the United States. It is negative in patients with visceral leishmaniasis, but it usually becomes positive after successful treatment. The test is typically positive in persons with cutaneous and mucosal leishmaniasis.

Liposomal amphotericin B (AmBisome, Fugisawa) is licensed in the United States for visceral leishmaniasis. It is highly effective, as is amphotericin B deoxycholate, but it is less toxic. Although it is the drug of choice in industrialized countries, its cost and availability have limited its use in impoverished endemic areas.

Sodium sibogluconate (Pentostam) and meglumine antimonate (Glucantime), both pentavalent antimony compounds, have been used for decades to treat leishmaniasis. Pentostam is available through the CDC Drug Service in the United States. These drugs are dosed on the basis of their pentavalent antimony content; Pentostam contains 100 mg of pentavalent antimony/mL and Glucantime contains 85 mg/mL. They are used to treat visceral leishmaniasis in some areas of the world, but antimony resistance and treatment failures are now common in the Indian subcontinent and other areas. In South America, and other areas where pentavalent antimony failures are infrequent, either Glucantime or Pentostam is given at a dose of 20 mg of

pentavalent antimony/kg body weight/day IV or IM for 28 days.

When relapses occur, they are usually observed within the first 6 months. They can be treated with a second course of the same drug or an alternative therapeutic regimen. Relapses are particularly common and toxicity greater with pentavalent antimony in persons with AIDS. Liposomal amphotericin B is the treatment of choice. It is important to optimize antiretroviral therapy. Suppressive antileishmanial therapy has also been used in those with AIDS, but there have been no controlled trials to suggest the optimal drug or regimen. Persons with visceral leishmaniasis in the developing world are severely wasted when they present and die from secondary bacterial or viral infections. Attention should focus on addressing their nutritional needs as well as treating secondary bacterial infections with appropriate antibiotics.

The emergence of pentavalent antimony resistance in India and other areas stimulated the search for new drugs. Miltefosine, a phosphocholine analog that is administered orally, is FDA-approved for the treatment of visceral leishmaniasis due to *L. donovani* in India and adjacent areas. Gastrointestinal effects are a problem but have not prevented the completion of therapy in most study patients. The drug is embryotoxic and contraindicated in pregnancy and breastfeeding. Resistance has been reported. Studies now underway should determine its role in the treatment of visceral leishmaniasis in Latin America and elsewhere.

Cutaneous leishmaniasis typically has a self-resolving course and is rarely life threatening. If lesions are small, few in number, cosmetically inconsequential, and not caused by *Leishmania* species associated with mucosal disease, they can be followed expectantly if there is evidence of self-healing or the lesions may be treated locally. Options include thermal therapy where it is available, cryotherapy for very small lesions, or topical administration of paromomycin (15%) in an effective vehicle. Intralesional injections with Pentostam have been used for uncomplicated Old World leishmaniasis, but the drug is currently available only for systemic administration in the United States. The choice of treatment depends on the infecting *Leishmania* species; the number, location, and size of the skin lesions; and the availability of the therapeutic modality. None of these are FDA approved. Cutaneous lesions respond slowly to any form of therapy and often take weeks to epithelialize. The result is typically an atropic, burn-like scar.

When lesions are large, cosmetically significant, or caused by *L.* (*V.*) *braziliensis* or related New World species associated with mucosal leishmaniasis, systemic oral or parenteral treatment is advisable. There are several options, but only miltefosine is FDA approved, and then only for *L. braziliensis* and two other New World species.

Historically, either Pentostam or Glucantime, 20 mg of pentavalent antimony/kg/day, for 20 days was used, but it is associated with substantial toxicity. Oral fluconazole has been effective in some settings. Fluconazole, 200 mg/day for 6 weeks, resulted in a high response rate in persons with cutaneous leishmaniasis due to *Leishmania major*, but *L. major* infections often heal spontaneously in a matter of weeks to months without treatment. While fluconazole at 200 mg/day has failed in other settings, persons infected with *L. braziliensis* have been successfully treated with high-dose fluconazole (8 mg/kg daily for 4–6 weeks) in northeastern Brazil. Amphotericin B deoxycholate and liposomal amphotericin are often effective, but costly and potentially toxic alternatives. Pentamidine has activity against *Leishmania* species, but its toxicity precludes its use for cutaneous leishmaniasis.

Persons with mucosal leishmaniasis are often treated initially with Pentostam or Glucantime, 20 mg of pentavalent antimony/kg/day for 28 days, usually in combination with pentoxifylline; failures and relapses are common. Alternatives include liposomal amphotericin B, amphotericin B deoxycholate, and miltefosine. Plastic surgical repairs in persons with mucosal lesions should be delayed for 12 months to ensure clinical cure because grafts may be lost if a relapse follows surgery.

203. Intestinal protozoa

Paul Kelly

Intestinal protozoal infection produces substantial morbidity and mortality in people of all ages, particularly in tropical and subtropical parts of the world. Amebiasis, giardiasis, cryptosporidiosis, and those infections associated with acquired immunodeficiency syndrome (AIDS) are important problems for health in many parts of the world, but some protozoa found in the human digestive system do not cause disease. Vaccines are not yet available for protection against these infections, and many are difficult to treat. The intestinal protozoa that produce important human infections are summarized in Table 203.1. There are differences between protozoa in their impact in patients with AIDS: cryptosporidiosis is an AIDS-defining infection, but neither the incidence nor the severity of amebiasis or giardiasis are affected by HIV.

Table 203.1 Intestinal protozoa

The sarcodina (amebae)	Pathogenic Nonpathogenic	*Entamoeba histolytica* *Entamoeba dispar* *Entamoeba moshkovskii* *Entamoeba chattoni* *Endolimax nana* *Iodamoeba butschlii* *Dientamoeba fragilis*
The mastigophora (flagellates)	Pathogenic Nonpathogenic	*Giardia lamblia* *Trichomonas hominis* *Chilomastix mesnili* *Embadomonas intestinalis* *Enteromonas hominis*
The ciliophora		*Balantidium coli*

The microspora		*Enterocytozoon bieneusi* *Encephalitozoon intestinalis*
Stramenopile		*Blastocystis hominis*

ENTAMOEBA HISTOLYTICA

Entamoeba histolytica causes dysentery, chronic colonic amebiasis, and hepatic amebiasis. The last topic is dealt with in Chapter 204, Extraintestinal amebic infection. Amebic dysentery is a syndrome of bloody diarrhea caused by invasion of the colonic wall by trophozoites of *E. histolytica*. It is common in many parts of the world, especially West and southern Africa, Central America, and south Asia. In the United States, 3000 to 4000 cases are reported each year. There is now consensus that the species formerly recognized as *E. histolytica* in fact comprises two species: *E. histolytica* and *Entamoeba dispar*. The first is the pathogenic protozoan long associated with human invasive disease and with hepatic amebiasis, and the latter is a morphologically identical nonpathogenic protozoan first recognized as the nonpathogenic zymodeme of *E. histolytica*. The latter does not require treatment, but it cannot be differentiated from *E. histolytica* morphologically. Diagnosis of invasive amebiasis is achieved by the identification of hematophagous trophozoites in very fresh stool smears or in colonic biopsies; the latter may also show typical flask-shaped ulcerations. Serologic testing using an immunofluorescent antibody test is now an important contribution to the diagnosis of a seriously ill patient, particularly in distinguishing colonic dilation resulting from amebiasis from that caused by ulcerative colitis. Serology does not distinguish between *E. histolytica* and *E. dispar*. Diagnosis using the polymerase chain reaction (PCR), which detects specific DNA sequences of genetic material, is increasingly available, and it does allow species identification.

Table 203.2 Drug treatment of amebiasis

		Adult dosage	Child dosage
Tissue infection			
First choice	Metronidazole[a]	750 mg TID for 10 d	50 mg/kg/d for 10 d[b]
	Tinidazole[a]	2 g/d for 3 d	60 mg/kg/d for 3 d
Second choice	Nitazoxanide	500 mg BID for 3 d	Age 2–3 years: 100 mg BID; age 4–11 years: 200 mg BID for 3 d
	Paromomycin	30 mg/kg/d for 10 d[b]	30 mg/kg/d for 10 d[b]
Luminal carriage			
First choice	Diloxanide furoate	500 mg TID for 10 d	20 mg/kg/d for 10 d[b]
Second choice	Paromomycin	30 mg/kg/d for 10 d[b]	30 mg/kg/d for 10 d[b]

[a] Must be followed by eradication of luminal carriage.

[b] In three doses.

Treatment of invasive amebiasis is shown in Table 203.2. Treatment can be divided into two stages: (1) eradication of tissue forms with metronidazole, tinidazole, or nitazoxanide and (2) eradication of luminal carriage with diloxanide furoate. Dehydroemetine and iodoquinol, used formerly for the treatment of amebiasis, are toxic and no longer used.

Intestinal amebiasis may be complicated by acute toxic colitis, presenting in a similar manner to the dilation of acute severe ulcerative colitis. The patient will be febrile and unwell, sometimes with signs of peritoneal irritation, and a plain abdominal radiograph will indicate dilation. Intravenous fluids must be given, the patient starved, and metronidazole and a third-generation cephalosporin given intravenously. Worsening dilation of the colon or perforation will necessitate surgery, but in the event of perforation, the outcome is poor. If treatment with metronidazole is started early in patients with severe amebic colitis, medical management should nearly always suffice, but surgery should not be delayed if perforation is impending.

Chronic amebiasis may be difficult to distinguish from intestinal tuberculosis or Crohn's disease but responds to metronidazole and diloxanide as above. Surgery is sometimes necessary because stricturing may persist.

GIARDIA LAMBLIA

Giardia lamblia infection, first recognized by Van Leeuwenhoek in 1681, is a cause of acute and persistent diarrhea and possibly malnutrition in children in many tropical and subtropical countries. It is also a well-recognized cause of travelers' diarrhea. In many cases it is self-limiting, but the course may be prolonged in immunoglobulin deficiencies. Asymptomatic infection is common. Diagnosis is by stool microscopy, although when this is negative and the clinical suspicion is strong, trophozoites may be detected in small intestinal fluid and mucosal biopsy specimens obtained by endoscopy (Figure 203.1). Fecal *Giardia* antigen enzyme-linked immunosorbent assays (ELISA) and PCR are now increasingly used in many routine diagnostic laboratories.

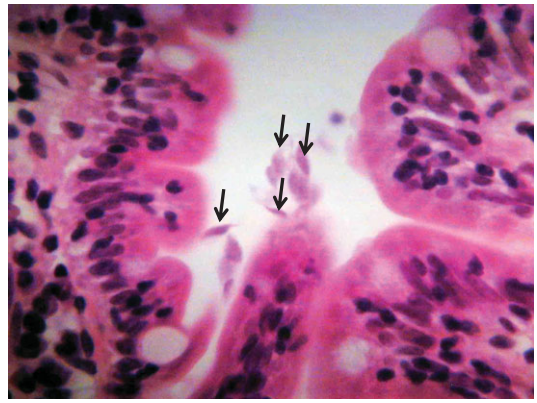

Figure 203.1 Trophozoites of *Giardia lamblia* in the lumen in a small intestinal biopsy (6-mm section stained with hematoxylin and eosin).

Several drugs are now available for the treatment of giardiasis but none are regarded as safe in pregnancy, and treatment failures are not uncommon, requiring a second and sometimes a third course of therapy. Five classes of chemotherapy are available (Table 203.3): nitroimidazoles (metronidazole and tinidazole), benzimidazoles (albendazole, secnidazole), nitazoxanide, nitrofurans (furazolidone), and paromomycin, which is the treatment of choice in pregnancy as it is not absorbed. If single agents fail repeatedly, combination therapy may be

Table 203.3 Drug treatment of giardiasis

Drug	Adult dosage	Child dosage	Efficacy
Metronidazole	500 mg TID for 3 d	5 mg/kg TID for 10 d (maximum 750 mg daily)	>90%
Tinidazole	2 g single dose	75 mg/kg single dose	>90%
Albendazole	400 mg daily for 5 d		>85%
Nitazoxanide	100–200 mg 2× daily		85%
Furazolidone	100 mg QID for 10 d	2 mg/kg TID for 10 d	>80%
Paromomycin	500 mg 3× daily for 5–10 d		

Table 203.4 Treatment of ciliophora, coccidia, and microsporidia

Organism	Drug regimen
Ciliophora	
Balantidium coli	Tetracycline, 500 mg QID for 10 d
Coccidia	
Cryptosporidium parvum	Nitazoxanide, 500 mg 2× daily for 3 d
Isospora belli	Trimethoprim–sulfamethoxazole, 1 DS tab PO QID for 10 d; Prophylaxis: 1 DS tab 3×/week
Sarcocystis species	As for *I. belli*
Cyclospora cayetanensis	Trimethoprim–sulfamethoxazole, 1 DS tab PO BID for 7 d
Microsporidia	
Enterocytozoon bieneusi	Fumagillin, 60 mg daily for 14 d
Encephalitozoon intestinalis	Albendazole, 400 mg BID for 14 d
Blastocystis hominis	The status of this organism as a pathogen is still the subject of controversy, so it is uncertain whether it requires treatment. It is our practice to attempt eradication with metronidazole, 750 mg TID for 10 d, when there are gastrointestinal symptoms and no other cause is apparent

tried, but there are few controlled data to guide drug choice, dose, or duration.

BALANTIDIUM COLI

Balantidium coli infection manifests as a severe, sometimes life-threatening, colitis indistinguishable from amebic dysentery. It is uncommon but occurs in Central and South America, Iran, Papua New Guinea, and the Philippines, usually in communities that live in close proximity to pigs, which are an important reservoir. Diagnosis is made by identification of the large trophozoites in feces or in rectal biopsies. Treatment is with tetracycline, 500 mg four times daily for 10 days (Table 203.4). Metronidazole and paromomycin are alternatives.

CRYPTOSPORIDIOSIS

Infection with *Cryptosporidium parvum* or *Cryptosporidium hominis* is likely to present as acute, self-limiting watery diarrhea in children or in travelers or as a waterborne epidemic. Most episodes require no specific therapy, but attention to fluid and electrolyte balance is important. Cryptosporidiosis is associated with persistent diarrhea, even in apparently immunocompetent children, and in human immunodeficiency virus (HIV)-infected individuals often persists until death. Cryptosporidiosis is also common in malnourished children in the tropics, irrespective of HIV infection. In patients with HIV-related diarrhea, cryptosporidiosis can be found in 10% to 30% of cases in industrialized countries and 10% to 40% of cases in tropical populations. However, since the introduction of highly active antiretroviral therapy (ART) with multidrug regimens, this infection is much less frequent in those regions where ART programs have been scaled up. It remains a significant clinical challenge in patients in the tropics, where patients often present with advanced AIDS or compliance is often poor. Diagnosis is usually made by microscopy of fecal smears using a modified Ziehl–Neelsen stain, which reveals the red-staining 5-μm oocysts, but ELISA and PCR tests are being adopted (Figure 203.2).

Although many drugs have been tried, only two have been shown to have any value in controlled trials: paromomycin and nitazoxanide. Hyperimmune bovine colostrum is a form of passive immunotherapy but is not in clinical use. Paromomycin (30 mg/kg/day in three doses)

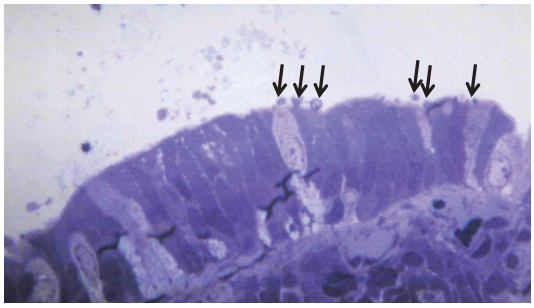

Figure 203.2 *Cryptosporidium* sp. trophozoites in small intestinal mucosa of an AIDS patient (semi-thin section stained with toluidine blue).

has been found to be of very limited efficacy. Nitazoxanide (1 g twice daily for 14 days) has been demonstrated to be effective in children and adults without AIDS in randomized controlled trials. Uncontrolled data from the US compassionate use program indicate that prolonged courses of 500 to 1500 mg nitazoxanide twice daily can be useful, but meta-analyses do not confirm this. There is still an urgent need for drugs which are effective in the severely immunocompromised host, and new drugs are in development. Interestingly, there is direct evidence that cryptosporidiosis can be prevented by simple measures: intensive hand washing reduced diarrheal disease, including cryptosporidiosis, in American AIDS patients, but to the author's knowledge this finding has not been replicated in a tropical setting.

ISOSPORA BELLI

Isospora belli is uncommon in industrialized countries but may be found in up to 40% of patients with HIV-related diarrhea in Africa. In HIV-infected individuals it causes a clinical syndrome of persistent diarrhea and wasting, which is indistinguishable from that attributed to other intracellular enteropathogenic protozoa (*C. parvum*, microsporidia). There were reports of isosporiasis before HIV infection appeared. Diagnosis rests on the identification in fecal smears of elongated, large sporocysts, which appear red with the modified Ziehl–Neelsen stain.

Trimethoprim–sulfamethoxazole (TMP–SMX) has been reported to be effective at a dosage of 160/800 mg four times daily for 10 days. In patients with AIDS, this needs to be followed with the same drug in a dose of 160/800 mg three times weekly indefinitely as prophylaxis against recurrence. Otherwise, recurrence is seen in 50% of patients with HIV infection at 2 months. An alternative drug is sulfadoxine–pyrimethamine (500/25 mg weekly) as secondary prophylaxis. Patients intolerant of sulfonamides could be given diclazuril, but only anecdotal evidence of its efficacy is available. In the author's experience it does not respond to nitazoxanide.

SARCOCYSTIS SPECIES

Sarcocystis infection, which may give rise to a persistent diarrhea, is treated in the same way as *I. belli*. This infection is uncommon.

DIENTAMOEBA FRAGILIS

Most infections with *Dientamoeba fragilis* are asymptomatic and do not require treatment. When required, treatment is as for amebiasis.

CYCLOSPORA CAYETANENSIS

Cyclospora cayetanensis is a newly recognized enteropathogen that causes travelers' diarrhea (especially in travelers to South America and Nepal) and foodborne outbreaks. In fecal smears, the oocysts resemble those of *C. parvum* in taking up carbol fuchsin in the modified Ziehl–Neelsen stain, but the oocysts are larger than *C. parvum* at 8–10 μm and they autofluoresce. Eradication is achieved using TMP–SMX (160/800 mg twice daily) for 7 days. If infection persists, then TMP–SMX should be continued for a further 3 to 5 days. In patients who are intolerant to TMP–SMX, ciprofloxacin can be used but it is less effective.

MICROSPORIDIA

Two microsporidia are pathogenic in the human gastrointestinal tract: *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* (formerly known as *Septata intestinalis*). These organisms have recently been reclassified and are actually fungi, but we consider them here as their clinical manifestations are so similar to intracellular protozoal infections such as cryptosporidiosis and isosporiasis. They are intracellular parasites, which generally infect severely immunocompromised individuals. The most common manifestation is a persistent diarrhea associated with weight loss, but a syndrome of sclerosing cholangitis is also described. Diagnosis relies on detection of the parasite in duodenal biopsies obtained at

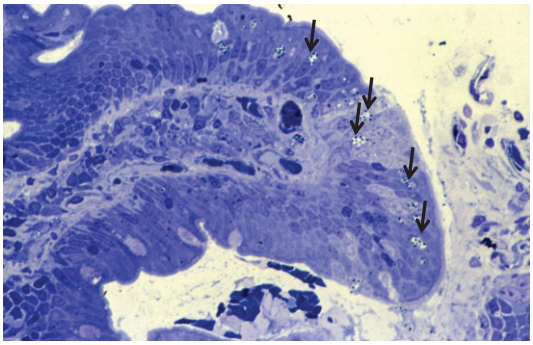

Figure 203.3 *Encephalitozoon intestinalis* in a small intestinal biopsy of an AIDS patient (semi-thin section stained with toluidine blue).

endoscopy (Figure 203.3) or on the finding of the spores in the feces using a variety of stains. *Encephalitozoon intestinalis* may cause a disseminated infection with renal spore excretion.

Treatment of *E. intestinalis* infection is with albendazole, 400 mg twice daily for 1 month, but maintenance treatment may be needed if relapse occurs following the cessation of therapy, although eradication may be achieved in some patients. *E. bieneusi* infection responds much less well, but fumagillin, 60 mg daily for 14 days, results in symptomatic improvement and parasite clearance in some patients. Fumagillin is toxic.

204. Extraintestinal amebic infection

Robert Huang and Sharon L. Reed

Extraintestinal manifestations of invasive amebic disease, although far less common than amebic colitis, are still a significant cause of morbidity and mortality worldwide, accounting for approximately 50 000 deaths annually. The most common presentation, amebic liver abscess, can be diagnosed clinically by its characteristic presentation in conjugation with appropriate epidemiologic risks and supported by serologic, antigen-based, or molecular testing. Without treatment, amebic liver abscess is almost always fatal, but with prompt and appropriate therapy, a cure is predictable. Other, more rare, manifestations of invasive amebiasis also occur and will be discussed as well. The foundation of successful invasive amebiasis treatment has been metronidazole or the more recently US Food and Drug Administration (FDA)-approved and structurally related agent, tinidazole.

AMEBIC LIVER ABSCESS

In addition to amebic colitis and its complications, extraintestinal manifestations of invasive *Entamoeba histolytica* infections can occur, led in frequency by amebic liver abscesses. An estimated 10% of the worldwide 40 to 50 million symptomatic amebic infections will either present as or be complicated by amebic liver abscess. Adult men are 7 to 10 times more likely to have amebic liver abscess than women, but there is no difference between the sexes in children. The different gender rates in adults are likely to be due to the protective effects of estrogen in women as suggested by animal models. As with other invasive amebic infections, amebic liver abscesses occur predominantly in the developing world with endemic disease seen in Central and South America, Africa, and Asia. A single amino acid substution in the leptin receptor has been linked to a 4-fold increase in susceptibility to invasive amebiasis, a genetic polymorphism which is overrepresented in many of the endemic countries. Travelers to countries with endemic disease are at risk for developing amebiasis and liver disease. Longer stays are associated with increased risk; however, liver abscesses have been reported in visitors with exposure as short as 4 days. Men who have sex with men (MSM) are an at-risk population in developed countries as the overall risk of intestinal amebiasis is greater in this group versus the general population. Finally, those with cell-mediated immune defects including chronic steroid users, pregnant women, alcoholics, the malnourished, and those with malignancy may also be at increased risk of invasive *E. histolytica* infection and subsequent liver abscess.

The clinical presentation of amebic liver abscesses has been well described in several large reviews. Fever and right upper quadrant pain are the most frequent complaints and also the most consistent findings on examination (Table 204.1). The duration of disease influences the symptoms, as patients with symptoms for more than 2 weeks tend to be afebrile and have weight loss and more focal abdominal pain. The classic finding of point tenderness in the right upper quadrant or intercostal tenderness has been frequently noted in earlier literature but is likely neither sensitive nor specific. At most,

Table 204.1 Clinical findings for patients with amebic liver abscess

Clinical findings	%
Fever	85%–90%
Right upper quadrant pain	84%–90%
Hepatomegaly	30%–50%
Weight loss	33%–50%
Diarrhea	20%–33%
Cough	10%–30%
WBC count >12 000/μL	80%
Elevated level of alkaline phosphatase	70%

Abbreviation: WBC = white blood cell.
From Petri and Singh. *Clin Infect Dis.* 1999;29:1117–1125.

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

only about one-third of patients have concomitant diarrhea or dysentery within the few weeks prior to their symptoms.

Approximately 80% of the liver abscesses are found in the right lobe of the liver, thus explaining the location of pain. The pain may also be located in the epigastrium, right lower chest, or the right shoulder tip (referred pain). Left-sided abdominal pain, corresponding to an abscess in the left lobe of the liver, is less common. Localized swelling or generalized hepatomegaly may be noted on exam depending on the size and location of the abscess or abscesses. Abscesses high in the right lobe of the liver may not result in hepatomegaly but, if of significant size, can lead to elevation of the right hemidiaphragm, which is evident on a chest radiograph.

Laboratory findings in a patient with amebic liver disease include leukocytosis (white blood cell [WBC] count $>12\,000/mm^3$), an elevated alkaline phosphatase, and, occasionally, elevated transaminases. It is uncommon to see an elevated bilirubin, and thus jaundice in a febrile patient with right upper quadrant pain should point the clinician toward another diagnosis. A mild degree of anemia (anemia of chronic disease) is present in many cases, particularly with symptoms for more than 2 weeks.

Figure 204.1 Contrast computed tomography (CT) scan image of an amebic liver abscess. The abscess appears as a hypoattenuating mass within the right lobe of the liver with an irregular, multiseptated rim with a thin rim of surrounding edema.

Diagnosis

Aspiration of a liver abscess is usually only indicated to rule out a pyogenic abscess or to prevent potential rupture as described below. Thus, the diagnosis of an amebic liver abscess is made in a patient with appropriate clinical symptoms, epidemiologic risk factors, and characteristic imaging findings confirmed by a positive serologic, antigen, or molecular test. Serologic testing for antibodies to *E. histolytica* is >80% sensitive in disease more than 1 week old, and nearly 99% sensitive in recovering patients. A negative test essentially rules out the diagnosis except in early infection (≤1 week). It is important to use an enzyme immunoassay (EIA) or agar gel dilution to test serology as an indirect hemagglutination often remains positive for years at high titer, and residents of an endemic region may have positive antibodies to *E. histolytica* that do not represent acute disease. Serum antigen detection tests to the *E. histolytica* Gal/GalNAc lectin gave a positive result in >95% of patients with amebic liver abscess in a study in Bangladeshi patients prior to treatment, comparing favorably to currently available serum antibody tests. Importantly, after treatment with metronidazole, circulating antigen levels were rarely detected (15%), making the test potentially useful for the diagnosis of acute disease in endemic countries. Molecular diagnosis using polymerase chain reaction (PCR) assays are highly sensitive and specific but remain primarily a research tool for the near future.

A number of imaging modalities are useful in supporting the diagnosis of amebic liver abscess. Chest radiographs in approximately 50% of patients with liver abscesses demonstrate an elevated right hemidiaphragm or other abnormality such as discoid atelectasis. Ultrasonography, computed tomography (CT) scanning, and magnetic resonance imaging (MRI) are all quite sensitive; however, the availability of these studies in amebiasis endemic areas is often limited. In the majority of cases, imaging demonstrates a single round or oval, homogeneous, hypoechoic lesion. Low-attenuation lesions with septations or an observable fluid level or debris may also be seen (see Figures 204.1 and 204.2). Unfortunately, although gallbladder and ductal abnormalities are seen more often in pyogenic liver abscess, there are really no specific radiographic features distinguishing

Table 204.2 Drug treatment of amebic liver abscess[a]

Drug of choice	Adult dose	Pediatric dose	Side effects
Metronidazole	750 mg IV/PO TID × 7–10 d	35–50 mg/kg/d in 3 doses × 7–10 d	Common: nausea, vomiting, metallic taste Occasional: peripheral neuropathy, vertigo, seizures, encephalopathy Disulfiram effect: nausea, vomiting with alcohol ingestion
Tinidazole[b]	2 g IV/PO qd × 5 d	60 mg/kg/d (maximum 2 g) × 5 d	Similar side effect profile as metronidazole: better tolerated with less nausea and vomiting

[a] All treatments should be followed by luminal amebicidal agent, described in text and detailed in Chapter 203, Intestinal protozoa.

[b] Used only as alternative to metronidazole.

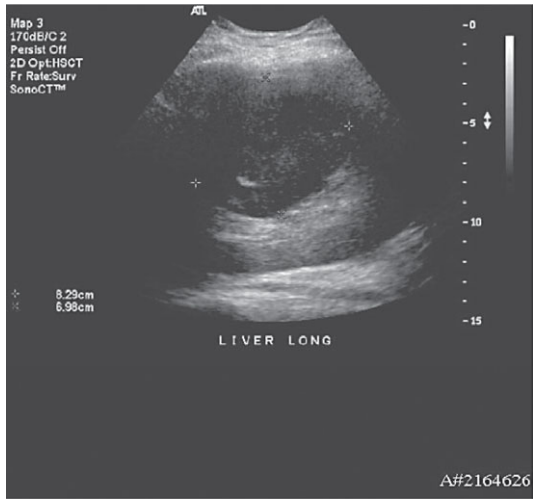

Figure 204.2 Ultrasound of the same amebic liver abscess as Figure 204.1.

pyogenic from amebic liver abscesses; therefore, imaging only serves as an aid to confirming the clinical suspicion of an intrahepatic process.

Aspiration of a liver abscess for the purpose of diagnosis is not generally recommended except in cases where immediate exclusion of a pyogenic abscess is clinically warranted. The classic gastronomic description of amebic pus as "anchovy paste" or "chocolate sauce" refers to the thick, acellular, proteinaceous debris consisting of necrotic hepatocytes and few polymorphonuclear cells obtained by successful aspiration. Amebic trophozoites are magenta colored by periodic acid–Schiff staining, making them easy to visualize, but finding trophozoites in an aspirate only occurs in 20% to 30% of cases, with a higher yield from the edge of the abscess.

The differential diagnosis of amebic liver abscesses includes pyogenic abscess, hepatocellular carcinoma, especially with necrosis, and echinococcal cyst. On imaging, the differential can often be narrowed to pyogenic abscess versus amebic liver abscess, with the clinical and radiographic findings being largely indistinguishable. Some epidemiologic differences may help to increase the likelihood of pyogenic liver abscess: age >50 years old, no sex predominance, underlying diabetes mellitus, biliary disease, and lack of travel to an endemic country. Nevertheless, these clues do not rule out amebic liver abscess, especially in a patient living in an endemic country.

Treatment

The treatment of amebic liver abscess worldwide has relied on the effective tissue amebicide, metronidazole. Metronidazole, a nitroimidazole compound, has been demonstrated in a number of trials to be effective in a dose of 750 mg three times daily for 7 to 10 days for adults and 35 to 50 mg/kg/day in three doses for 7 to 10 days for children (Table 204.2). Metronidazole is generally well tolerated but the disulfiram-like reaction to alcohol is important to mention to patients. Minor side effects such as nausea, vomiting, anorexia, and a metallic taste occur more frequently than rare neurologic adverse effects such as vertigo, seizures, and encephalopathy. The drug should be discontinued if these latter effects or, rarely, neutropenia occur. Long-term use of metronidazole is also known to cause peripheral neuropathy, but the duration of therapy for invasive amebic disease should not approach that at which this adverse event occurs.

The related imidazole compound, tinidazole, has been reported as effective as a single 2-g dose for treatment of liver abscess in South Africa. Tinidazole has now been approved by the FDA

after its use for years in other countries. The recommended dose for amebic liver abscess is 2 g/day for 3 to 5 days in adults and 50 mg/kg/day for 3 to 5 days in children. It is generally better tolerated than metronidazole and offers a shorter course; however, it is more expensive and less well studied. The imidazoles are more than 90% effective in the treatment of amebic liver abscess. Although clinical cases of resistance have been demonstrated in the related protozoa, *Giardia lamblia*, and resistance can be demonstrated in vitro, no clinical cases of metronidazole-resistant amebiasis have been documented. Treatment with these agents typically results in defervescence, decreased abdominal pain, and normalization of the WBC count within 3 days.

Therapeutic aspiration of amebic liver abscesses is now typically reserved for several specific circumstances. Disease not responding to 3 to 5 days of medical therapy with persistent fever or pain, imminent rupture of an abscess >15 cm, or a left lobe abscess that may rupture into the pericardium have all been cited as reasons to drain abscesses. Blind needling of the liver for the purposes of diagnosis or treatment is dangerous and ultrasonographic or CT-guided aspiration is recommended in all instances when available.

All treatment regimens with a tissue amebicide should be followed by treatment with a luminal amebicide to eliminate intestinal carriage of the organism that could lead to relapse if not treated. Paromomycin, a nonabsorbed aminoglycoside, taken for 7 days is the preferred luminal amebicide in the United States. It is safe in pregnancy, has minimal gastrointestinal side effects, and ototoxicity and nephrotoxicity rarely occur. Diloxanide furoate is also effective and well tolerated and has few side effects but is not commercially available in the United States. Iodoquinol is likewise effective but has some serious side effects such as optic neuritis and peripheral neuropathy, and requires a 20-day course. Nitazoxanide, a 5-nitrothiazolyl derivative, is active against a range of protozoa and is approved by the FDA for the treatment of diarrhea caused by *Cryptosporidium parvum* and *G. lamblia* in children. Its activity against *E. histolytica* has been demonstrated in vitro, and one double-blind, placebo-controlled trial suggested efficacy as well; however, it has not been directly compared to the standard luminal amebicides already mentioned.

The usual response to medical therapy of an amebic liver abscess is rapid resolution of fever and pain. There is no reason to get a follow-up ultrasound early in the course, as lesions may actually enlarge acutely, but they ultimately completely resolve within a year. Serology by EIA typically reverts to negative within 6 months.

AMEBIC PLEUROPULMONARY DISEASE

The most common pulmonary manifestation of invasive amebiasis is development of a serous, sympathetic effusion in the right pleural cavity due to a right-sided liver abscess. Rupture of a liver abscess into the chest cavity can lead to empyema, producing signs such as cough, dyspnea, and pleuritic chest pain. Thoracentesis will reveal the classic anchovy paste fluid described above. Classically, patients who develop bronchopleural fistula will expectorate the contents of the liver abscess. Although unpleasant, prior to amebicidal agents this occurrence was deemed a good prognostic sign, as it was an effective means of draining the abscess. In addition, hematogenous spread of amebic trophozoites can rarely cause disease in the lung parenchyma leading to consolidation and sometimes lung abscess. Treatment of pleuropulmonary disease involves the use of a tissue amebicide, such as metronidazole, and, in the case of empyema, drainage with a chest tube. Amebic pneumonia and lung abscesses from hematogenous spread are successfully treated with metronidazole alone.

AMEBIC PERICARDITIS

The most serious complication of a left-lobe amebic liver abscess is rupture into the pericardium leading to pericarditis and, potentially, cardiac tamponade. In one large series, the incidence of pericardial rupture was approximately 1% of all liver abscess cases. A left-lobe liver abscess threatening the pericardial sac may cause irritation and a serous effusion. The rapidity of leakage of amebic pus into the pericardial sac determines both the signs and symptoms that develop. A slow leak gives more insidious symptoms of gradually increasing shortness of breath, unmitigated fever, and patient deterioration, whereas a rapid rupture into the pericardium may cause cardiac tamponade and the associated chest pain, tachypnea, pulsus paradoxus, elevated neck veins, and hypotension.

The evaluation of amebic pericarditis begins with establishing the diagnosis of an invasive amebic infection with positive serologic testing in a patient with left-lobe liver abscess and a compatible epidemiologic history. An

electrocardiogram will show evidence of pericarditis, and chest radiography demonstrates an elevated and immobile left diaphragm. Confirming the diagnosis is only definitively accomplished by aspiration of the pericardium, which, along with effective tissue amebicides, is the treatment of choice. A concomitant large liver abscess should also be aspirated and repeat aspirations performed if needed to eliminate the risk of further pericardial accumulation. Fibrous constriction is unusual after the above treatment, and surgical treatment is unnecessary in most cases.

AMEBIC PERITONITIS

In about 2% of amebic liver abscesses, intraperitoneal abscess and peritonitis complicate the case. The associated physical exam findings of an acute abdomen are usually present. Compared to amebic peritonitis due to perforation of the colon from amebic colitis, patients with ruptured liver abscesses and peritonitis have better outcomes because there is not concomitant colonic bacterial flora contaminating the peritoneum. Treatment of amebic peritonitis due to liver abscess rupture is with metronidazole plus therapeutic paracentesis to drain infected collections.

OTHER MANIFESTATIONS OF INVASIVE AMEBIC DISEASE

Although very rare, amebic brain abscesses can occur by hematogenous seeding of trophozoites and may present with altered mental status, headache, and focal neurologic signs in a patient with known amebiasis. Computed tomography scanning of the head reveals often multiple space-occupying lesions, which, early in the course of disease, may be low-attenuation circumscribed areas without a clear rim or enhancement. Treatment involves an extended course of metronidazole, which has good central nervous system penetration, and possible surgical drainage depending on the size of the lesion(s) and severity of the symptoms.

Amebic splenic abscesses, also resulting from hematogenous spread of amebic trophozoites, can be visualized with ultrasound or CT scan and are treated medically with metronidazole. Splenectomy is occasionally required.

Urinary tract amebiasis, manifesting as perinephric abscesses, is again due to hematogenous spread of amebic trophozoites and treated with metronidazole. Genital amebiasis is more common in women than men, with vaginitis, vulvovaginal amebiasis, cervicitis, and salpingitis all having been reported. These cases may be sexually transmitted; consequently, ulcerative penile lesions in a sexual partner should be evaluated for possible amebiasis. Invasive carcinoma of the penis and carcinoma of the cervix are often initially suspected as the clinical appearance of the amebic ulcerative lesions mimics that of these malignancies. An epidemiologic study in Japan found a link between genital amebiasis and MSM engaging in anal sex with partners with amebic colitis. The treatment for these manifestations of the disease is again with metronidazole, and sexual partners should always be treated as well. Finally, cases of cutaneous amebiasis, presenting as painful ulcers, in both children and adults have also been described in the literature. These presentations are often, but not always, associated with intestinal amebiasis and respond to metronidazole.

205. Principles of antibiotic therapy

John S. Czachor

Over the last three decades, there has been the recognition of a very disturbing trend of antibiotic resistance amongst a wide variety of pathogens that are causing serious disease in patients residing in the community, in long-term care facilities, and in hospitals. Especially troublesome have been *Streptococcus pneumoniae* that may be resistant to penicillin and/or fluoroquinolones; *Staphylococcus aureus*, including all methicillin-resistant *S. aureus* (MRSA) variants, and rarely, those that may be resistant to vancomycin, linezolid, or daptomycin; *Enterococcus* spp. that are not susceptible to ampicillin, vancomycin, linezolid, or daptomycin; extended-spectrum β-lactamase-producing (ESBL) *Escherichia coli* and *Klebsiella pneumoniae* resistant to numerous agents; multidrug-resistant (MDR) *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, and *Acinetobacter* spp.; carbapenem-resistant *K. pneumoniae*, *E. coli*, and other Enterobacteriaceae; clindamycin-resistant *Bacteroides fragilis*; and *Mycobacterium tuberculosis* organisms resistant to all available drugs.

The pharmaceutical industry has responded to this grave concern and has developed a variety of agents, for example quinupristin–dalfopristin, linezolid, daptomycin, telavancin, and dalbavancin, which generally inhibit the growth of gram-positive bacteria; ceftaroline and ceftibiprole, which are cephalosporin class drugs that inhibit gram-positive organisms, including MRSA, and gram-negative bacteria; and tigecycline, which possesses inhibitory activity for a wide range of gram-positive, gram-negative, and anaerobic bacteria. As these antibiotics are used more frequently, it may be easier to precisely establish the indications for their use, their potential to cause toxicities and drug–drug interactions, and to identify *the* preferred agent for a specific infection.

Another event that has merited attention is the continuously evolving novel indications for antibiotics for both infectious and noninfectious disorders. The newer macrolides have anti-inflammatory properties, and their use in cystic fibrosis and emphysema continues to be delineated. The use of ampicillin combined with ceftriaxone has recently been championed to treat infective endocarditis caused by *Enterococcus faecalis* with high level reistance to aminoglycosides. Finally, there are a number of antimicrobial compounds that are prescribed for nonbacterial dermatologic conditions, such as dapsone for dermatitis herpetiformis.

When selecting an antibiotic, the clinician must reflect on a number of issues. Some of the more common factors that merit consideration include the patient's drug allergy history; the relative safety of the medication; the potential of the antibiotic to cause a significant drug–drug interaction; the mechanism of the drug's elimination from the body; the agent's historical "track record" in the therapy of the specific infection being treated; the route of administration of the antibiotic; and the cost of the medication. For the oral administration of antibiotics there are the additional concerns of patient compliance and adequate drug absorption.

PHARMACOKINETICS AND PHARMACODYNAMICS

The term pharmacokinetics refers to the disposition of an antibiotic throughout the human body. This encompasses such principles as absorption, bioavailability, distribution, protein binding, metabolism, and elimination. Pharmacodynamics refines the concept of pharmacokinetics by describing the interaction between the concentration of the antibiotic at the site of the infection over time and its subsequent effect on the infection itself. Pharmacodynamics is useful for establishing optimum dosing regimens. The absorption of most oral antibiotics occurs by passive diffusion in the small intestine. Some antibiotics, including

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

vancomycin, aminoglycosides, and aztreonam, are not adequately absorbed when given orally. On occasion, this can be advantageous. Oral neomycin can be prescribed as a preoperative preparation prior to large bowel surgery or the treatment of hepatic encephalopathy, whereas the poorly absorbed oral vancomycin and fidaxomicin are used for the therapy of *Clostridium difficile*-related colitis. Other drugs, such as cefpodoxime proxetel and cefuroxime axetil, are administered as prodrugs to facilitate absorption. Food interferes with the absorption of some antimicrobials, for example, penicillin, ampicillin, cephalexin, tetracycline, and azithromycin.

A fundamental tenet of antimicrobial activity is that it must achieve therapeutic concentrations at the tissue source of the infection. Multiple factors influence the distribution of antibiotics from plasma to these sites: the nature of the capillary bed (those fenestrated by small pores versus those unfenestrated capillaries of the brain, leptomeninges, and vitreous humor), the lipid solubility, the degree of protein binding (as only unbound drug is antibacterially active and capable of diffusing across capillaries), and the presence of active transport pumps (located in the choroid plexus of the brain, retina, kidneys, and biliary ducts).

Antibacterial agents are eliminated from the body through hepatic and biliary excretion (ceftriaxone and piperacillin), hepatic metabolism (clindamycin, chloramphenicol, metronidazole, erythromycin, sulfonamides, some tetracyclines, isoniazid, rifampin, linezolid), and predominantly renal excretion (most penicillins and cephalosporins, imipenem, aminoglycosides, nitrofurantoin, most tetracyclines, ofloxacin, vancomycin, trimethoprim–sulfamethoxazole [TMP–SMX], daptomycin). It is essential that the clinician be aware of renal compromise from congestive heart failure, hypertension, diabetes, medication, and physiologic alteration with age, because this will mandate a dosage reduction for those compounds predominantly eliminated by renal excretion. The estimated glomerular filtration rate (GFR; using the Cockcroft–Gault equation or the Modification of Diet in Renal Disease [MDRD] equation) has traditionally been used to help determine appropriate drug doses for antimicrobials eliminated primarily by renal excretion when the measured creatinine clearance is not available. A newer formula, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI), may be the best to estimate GFR.

Concentration-dependent antimicrobial agents function such that optimal bacterial killing occurs while the concentration of the antibiotic is above the minimum inhibitory concentration (MIC) of the organism. The aminoglycosides are one example of this type and are usually administered as once-daily dosing (unless prescribed for synergistic purposes), taking advantage of the observation that the ratio of the maximum peak drug concentration to organism MIC (8 to 12) correlates with clinical response. Other concentration-dependent antimicrobials include fluoroquinolones, daptomycin, and metronidazole. Alternatively, those compounds that are concentration independent or time dependent measure their success by the percentage of time the drug concentration exceeds the MIC of an organism. Drugs in this class include vancomycin, clindamycin, the macrolides, and the β-lactam group. There may be some benefit for continuous intravenous administration of the β-lactam antibiotics, thereby maintaining sustained drug levels above the MIC of the pathogen, particularly in the severely ill or immunocompromised patient.

The postantibiotic effect (PAE) is another pharmacodynamic concept that may impact antimicrobial choice. This refers to the persistent suppression of bacterial regrowth following limited exposure to an antibiotic and can be considered the time it takes for the organism to recover from this exposure. Classically, drugs that affect protein synthesis or nucleic acid synthesis, such as the fluoroquinolones, aminoglycosides, tetracyclines, macrolides, chloramphenicol, and rifampin, have significant PAEs against gram-negative organisms, although the only β-lactam antibiotics that share this property are the carbapenems.

SELECTION OF THERAPY

Table 205.1 delineates some of the more important host and drug features that influence antibiotic selection. Additional concerns relate to adherence to the therapeutic regimen and cost of the medication. Antibiotics that can be administered infrequently lend themselves to out-of-hospital administration. Daptomycin, ertapenem, televancin, and ceftriaxone can usually be infused as infrequently as once a day. Dalbavancin is a new once-weekly administered drug for skin and soft-tissue infections. The development of newer oral antimicrobial agents that can be given as infrequently as once or twice per day achieves

Table 205:1 Selection of therapy

Host factor	Special antibiotic concern
Drug allergy	Safety record
Site of infection	Success record
Pregnancy	Most likely organism(s) and
Epidemiologic information	susceptibility
Renal function	Bactericidal/bacteriostatic
Recent antibiotic exposure	Penetration into privileged sites
Infection acquisition	(CNS, endocardium)
(community/ECF/hospital)	Potential to cause major
Concomitant medication	untoward event

Abbreviations: CNS = central nervous system; ECF = extended care facility.

Tuberculosis
Disseminated *Mycobacterium avium* complex
Helicobacter pylori
Endocarditis (α-hemolytic streptococcus, enterococcus)
Life-threatening infection caused by *Pseudomonas aeruginosa*
Empiric treatment -Pneumococcal meningitis until susceptibility confirmed -Febrile, severely neutropenic host -Polymicrobic infection -Life-threatening infection with inapparent source

enhanced compliance. Compounds such as the fluoroquinolones, metronidazole, and linezolid have excellent absorption, resulting in high serum levels without the need for intravenous administration. Some medications, although still available, including chloramphenicol and erythromycin estolate, are infrequently prescribed, having fallen out of favor due to adverse effects, unfavorable pharmacokinetics and/or pharmacodynamics, or a limited spectrum of activity.

Antibiotic combinations are sometimes used to manage selected infections (Table 205.2). There are potential disadvantages, however, to the administration of antibiotic combinations such as increased untoward events, heightened costs, and suprainfection.

PRACTICE GUIDELINES AND ANTIBIOTIC STEWARDSHIP

In the past, with few exceptions, choosing an antibiotic has been left to the whims of clinicians. Seldom has the optimal duration of antibacterial treatment been defined by evidence-based medicine. Practice guidelines have emerged in response to questions regarding the quality, consistency, and the expense of medical care. Guidelines are generally created based upon the best available scientific evidence melded with expert opinion, cohesively assembled in a usable format for practitioners. Selected medical societies and organizations, as well as easily accessible websites, have become the repositories for the recommended information. Access to these guidelines has helped to transform how medicine is practiced today. Guidelines for various infectious conditions already exist, whereas others are being created and refined.

Just as important as the guidelines has been the recognition of the need for optimal, cost-effective, and rational use of antibiotics. Stewardship has evolved from guidelines to encompass antimicrobial utilization for all conditions and can be found in hospitals, long-term care facilities, long-term acute care facilities, ambulatory surgical centers, dialysis centers, and other medical settings. Institutions employing stewardship are coordinating interventions, often in conjunction with pharmacy assistance, to promote appropriate antibiotic selection, as well as their proper dose, duration, and route of administration. Benefits of antibiotic stewardship include improved clinical outcomes, reduced medical costs, fewer toxic and adverse effects, and decreased selection of antibiotic-resistant microorganisms.

SPECIAL POPULATIONS

The pregnant patient

Physiologic changes in the urinary tract and complications of parturition predispose the pregnant woman to urinary tract infections, as well as chorioamnionitis and endometritis. Antibiotic selection for the pregnant woman must take into consideration the potential for drug-induced toxicities for both the woman and her developing fetus. Animal studies and epidemiologic data (generated from pregnant women who were exposed to antibacterial agents because of clinical need) suggest that penicillins, including those in combination with a β-lactamase inhibitor, cephalosporins, aztreonam, erythromycin, azithromycin, clindamycin, and metronidazole have not demonstrated human fetal risk. Sulfonamides should be avoided late in pregnancy because of the potential to develop neonatal kernicterus. Chloramphenicol should not be administered to

Table 205.3 Adverse drug reaction

Drug	Untoward event
Aminoglycoside	Nephrotoxicity, ototoxicity
Amoxicillin–clavulanate (chronic administration)	Hepatotoxicity
TMP–SMX	Blood dyscrasias, hyperkalemia
Fluoroquinolone	Seizure
Doxycycline	Esophageal stricture/ulcer
Nitrofurantoin (chronic administration)	Pulmonary fibrosis, hepatitis, agranulocytosis

Abbreviation: TMP–SMX = trimethoprim–sulfamethoxazole.

Table 205.5 Drugs requiring dosage alteration during CRRT[a]

Amikacin	Penicillin
Ampicillin/sulbactam	Piperacillin
Cefazolin	Piperacillin–tazobactam
Ciprofloxacin	Ticarcillin–clavulanate
Daptomycin	Tobramycin
Gentamicin	TMP–SMX
Levofloxacin	Vancomycin

[a] Dose reduction as compared to normal renal function.
Abbreviations: CRRT = continuous renal replacement therapies; TMP–SMX = trimethoprim–sulfamethoxazole.

the mother near term as the newborn does not possess the appropriate liver enzyme to metabolize this drug, and hence the "gray baby" syndrome can result. The aminoglycosides gentamicin, tobramycin, and amikacin should not be administered to pregnant women, especially eclamptic women, unless there is a compelling reason. If they must be prescribed, serum concentrations must be monitored carefully.

The fluoroquinolones are not recommended for use in pregnancy because of their adverse effects on developing cartilage seen in animal studies. Tetracyclines are contraindicated in pregnant women because these compounds can interfere with normal development of teeth and bones in the fetus and have caused hepatorenal failure and death, particularly when administered intravenously to treat pyelonephritis, in pregnant women.

The elderly patient

There are a number of factors that distinguish the administration of antibiotics in elderly patients: concern about compliance with the medication because of poor memory, impaired vision, diminished hearing, or difficulty in opening child-resistant containers; the decrease of renal function with normal aging, and the need to make appropriate dosage adjustment of medications to prevent antibiotic-related toxicities; the potential for drug–drug interactions, as many geriatric patients take numerous medications daily; and the presence of concomitant medical disorders that can adversely influence antibiotic distribution and penetration. Elderly patients appear to experience adverse drug reactions from antibacterial compounds more frequently than younger patients do (Table 205.3).

Table 205.4 Drugs not requiring dosage alteration during continuous renal replacement therapies

Aztreonam	Linezolid
Azithromycin	Meropenem
Cefepime	Metronidazole
Ceftriaxone	Moxifloxacin
Clindamycin	Oxacillin
Doxycycline	Quinupristin–dalfopristin
Gatifloxacin	Rifampin
Imipenem	

ANTIBIOTIC USE IN CONTINUOUS RENAL REPLACEMENT THERAPY

For critically ill patients with infection, acute renal insufficiency often develops. Acute renal failure is associated with increased morbidity and mortality in patients with sepsis. Continuous renal replacement therapy (CRRT), an alternative to traditional hemodialysis and better tolerated by hemodynamically unstable patients, decreases the incidence of adverse biomarkers. Appropriate dosing of antimicrobial agents for patients receiving CRRT remains poorly defined, as the pharmacokinetics of drug removal in critically ill patients undergoing CRRT is complex. Those antibiotics with low protein-binding capacity and/or poor tissue penetration have enhanced removal. Mechanical or operational factors associated with CRRT play a role in antibiotic therapy in these patients as well, and increasing the blood flow or dialysate flow rate of CRRT may increase drug clearance. Tables 205.4 and 205.5 list antibiotic dose alterations for patients with CRRT.

ROUTE OF ADMINISTRATION

Antibiotics are administered intravenously when the patient has systemic perfusion issues (septic shock, hypotension), has bacterial infection at a

unique or protected site (e.g., leptomeninges, endocardium, a deep neck infection, epiglottitis, endophthalmitis, myopericarditis, mediastinitis, septic thrombophlebitis), has an infection that is imminently life endangering (e.g., meningococcemia, Rocky Mountain spotted fever, plague, bacteremia), has an infection that precludes oral administration because of nausea/vomiting or impaired function of the gastrointestinal tract (peritonitis, appendicitis, ascending cholangitis, pancreatic abscess), or has an infection that cannot be managed with an oral compound. Traditionally, physicians have prescribed an intravenous antibiotic simply because a patient was admitted to the hospital. However, the decision to hospitalize a patient does not automatically dictate that the antibacterial therapy must be administered intravenously. Unless one of the indications previously listed is present, some serious infections can be successfully managed by oral antibiotics.

ADVERSE REACTIONS

Antibiotic-induced untoward events are a concern not only because they result in host injury but also because these adverse events interrupt and complicate treatment, thereby requiring the administration of alternative and often more expensive and potentially toxic medication. Antibiotic-induced untoward events can also serve as a source of medical litigation.

Adverse events attributed to antibiotics are usually caused by three mechanisms: exaggerated response to the known pharmacologic effects of the drug, immunologic reactions to the drug or its metabolites, and toxic effects of the medication or its metabolites. Many of the antibiotic-related adverse events are initiated by an extension of the drug's normal pharmacology, and these events are often avoided by appropriate dosage adjustment.

In addition to the direct influence of the antibiotic, host factors such as genetic constitution, integrity of drug elimination mechanisms, and concomitant medical disorders can affect the frequency and severity of antibiotic-induced untoward events. For example, with human immunodeficiency virus (HIV)-infected patients, TMP–SMX causes more non-dose-related gastrointestinal intolerance, fever, and altered liver function, while ampicillin-induced rash is more common in those patients with infectious mononucleosis.

The penicillin family of drugs is usually well tolerated, but on occasion these drugs can cause hypersensitivity events, including fever, rash (maculopapular and urticarial), anaphylaxis, exfoliative dermatitis, erythema multiforme, serum sickness, and hemolytic anemia. When administered intravenously in high doses, particularly to patients with renal impairment, they have the potential to cause central nervous system toxicity, manifested by myoclonic jerks, seizures, and coma.

The most notorious side effects of clindamycin are diarrhea and *C. difficile*-related colitis. This drug has rarely caused drug fever, blood dyscrasias, and hepatotoxicity. Doxycycline has caused diarrhea and, on occasion, photosensitivity, rash, hepatitis, and, particularly in elderly patients, esophageal ulcerations and strictures.

Uncommon adverse events attributed to vancomycin include rash, fever, nephrotoxicity, ototoxicity, and reversible, transient hematopoietic toxicity. The most dramatic side effect is the red man syndrome, a nonimmunologically mediated reaction consisting of pruritis and erythema with or without hypotension, which appears to be dependent on dose, frequency of administration, and rate of infusion. With regard to the newer antibiotics designed to manage gram-positive infections caused by vancomycin-resistant organisms, quinupristin–dalfopristin can cause severe arthralgias and myalgias; chronic administration of linezolid has produced myelosuppression, optic neuropathy, and peripheral neuropathy; infusion of daptomycin has elicited myopathy and paresthesias/dysesthesias, and rarely, eosinophilic pneumonitis; and tigecycline has been associated with nausea, vomiting, and headache. Gastrointestinal symptoms are the most common untoward events attributed to the administration of the new semisynthetic lipoglycopeptide dalbavancin.

Rash, fever, and gastrointestinal adverse events are the most common side effects produced by TMP–SMX. Additional rare untoward events include nephrotoxicity, hyperkalemia, hematologic derangements (neutropenia, thrombocytopenia, agranulocytosis, aplastic anemia, megaloblastic anemia), hepatitis, and central nervous system events, including headache, insomnia, vertigo, ataxia, and aseptic meningitis.

Adverse events attributed to the macrolides have included nausea, vomiting, abdominal pain, diarrhea, and rarely antibiotic-associated colitis, pancreatitis, cholestatic jaundice, acute hepatitis,

and reversible ototoxicity. Azithromycin and clarithromycin have demonstrated the propensity to prolong the QTc interval, resulting in cardiac arrhythmias and sudden death.

The most common adverse events associated with the administration of the fluoroquinolones are gastrointestinal symptoms, nervous system toxicity (headache, dizziness, insomnia, agitation, hallucinations), and allergic reactions, including pruritis and rash. Rare adverse events attributed to the quinolones include seizures, elevation of liver enzymes, and tendinopathy. Administration of the fluoroquinolones has been associated with an increased risk of dysglycemia.

There has been renewed interest in the old antibiotic, polymyxin E (colistimethate sodium), as therapy for patients with life-endangering infections caused by drug-resistant *Pseudomonas aeruginosa* and *Acinetobacter baumannii*. This agent has the potential to elicit both neurotoxic side effects and nephrotoxicity.

ANTIBIOTIC ALLERGY

Antibiotic-induced allergic reactions are immunologically mediated and most commonly involve the skin as pruritus, a maculopapular eruption, or urticaria. More significant antibiotic-induced allergic reactions include erythema multiforme major (Stevens–Johnson syndrome), toxic epidermal necrolysis, exfoliative dermatitis, angioedema, and anaphylaxis. Antibiotic-induced allergic reactions are not confined to the skin: amoxicillin–clavulanate and macrolides have caused cholestatic liver injury, and high-dose administration of penicillins and cephalosporins have caused hemolysis and cytopenias.

Among the most feared allergic reactions to penicillins and cephalosporins are angioedema and anaphylaxis. These events are usually attributed to drug-specific immunoglobulin E (IgE) antibodies from prior drug administration, but these serious untoward events can also result from direct release of mast-cell mediators following the first dose of antibiotic. Vancomycin and fluoroquinolones can also cause direct mast cell release in the absence of drug-specific IgE antibodies. Skin testing has been very accurate for identifying penicillin-related IgE antibodies and for determining the risk for patients experiencing an immediate reaction (see Chapter 210, Hypersensitivity to antibiotics).

If a patient has a history of a presumed IgE-mediated reaction to a penicillin (angioedema, anaphylaxis), it may be best to avoid a cephalosporin, although rates of cross-reactivity are approximately 2% and the risk lessens as the compounds go from first generation to fourth generation. It is noteworthy to remember that any drug desensitization can be complicated by severe allergic reactions. Although structurally similar to the β-lactam antibiotics, aztreonam can be safely administered to patients who have experienced an anaphylactic reaction following the administration of a member of the penicillin family. It is considered potentially harmful to administer a carbapenem to patients with a history of immediate hypersensitivity to penicillins; however, recent investigation suggests that those patients with negative skin testing to imipenem–cilastatin can safely be offered this antibiotic.

DRUG–DRUG INTERACTIONS

Drug–drug interactions can be subtle or life-endangering, and they occur when one drug modifies the pharmacokinetics (absorption, distribution, metabolism, or excretion) or pharmacodynamics of another drug. Magnesium antacid reduces the absorption of nitrofurantoin, food diminishes the absorption of azithromycin, and antacids, sucralfate, ferrous sulfate, and zinc alter the bioavailability of oral tetracyclines and quinolones. Oral antacids lower the plasma concentrations of cefditoren. The angiotensin-converting enzyme inhibitor quinapril has a high concentration of magnesium, and it impedes the absorption of the quinolones. Suppression by oral tetracyclines, erythromycin, or TMP–SMX of upper intestinal bacteria that inactivate digoxin can result in digoxin-induced toxicity. Administration of doxycylcine has been associated with failure of oral contraceptive preparations. Alcohol ingestion in patients receiving metronidazole can result in a disulfiram-like reaction.

Drug–drug interactions have not been a major concern for patients receiving the penicillins, carbapenems, aztreonam, and the cephalosporins. Theophylline and cyclosporine can reduce the threshold for seizures in patients receiving imipenem, and meropenem decreases the serum concentrations of valproic acid to subtherapeutic levels in patients with seizure disorders. There is the potential for enhanced aminoglycoside-induced nephrotoxicity and/or ototoxicity when patients receive vancomycin, amphotericin B, cyclosporine, cisplatin, and ethacrynic acid.

Ciprofloxacin has the potential to inhibit the metabolism of theophylline through its effect on the enzymes of the cytochrome P450 system and

produce theophylline toxicity. Ciprofloxacin can also alter cyclophosphamide pharmacokinetics in patients with non-Hodgkin's lymphoma. There is a potential concern when fluoroquinolones are used to treat patients taking medications (antipsychotics, tricyclic antidepressants, and antiarrhythmics) that predispose to the development of torsades de pointes. Levofloxacin and moxifloxacin have been associated with enhancement of the effect of warfarin.

Macrolides are extensively metabolized by cytochrome P450 3A isozymes (CYP3A), and when these antibiotics are coadministered with medications that are strong inhibitors of CYP3A, such as azole antifungal drugs, diltiazem, verapamil, and protease inhibitors, sudden cardiac death can occur. Coadministration of sirolimus and erythromycin in transplant recipients increases the blood concentrations of the immunosuppressant. Clarithromycin is oxidized by the cytochrome P450 system, and this compound results in decreased clearance of those other agents given concurrently that are metabolized by the same enzyme system. Administration of clarithromycin to a patient taking a statin (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor) other than pravastatin can result in rhabdomyolysis. Coadministration of digoxin and clarithromycin can result in digitalis intoxication.

The serotonin syndrome (fever, agitation, mental status changes, myoclonus, and tremors) has been associated with the coadministration of linezolid and medications that increase concentrations of serotonin in the central nervous system, such as the selective serotonin reuptake inhibitors. If the patient's infection requires linezolid therapy, the selective serotonin reuptake inhibitor should be discontinued, and the patient monitored for the serotonin syndrome. Coadministration of TMP–SMX with phenytoin, glipizide, methotrexate, and thiazide diuretics has caused phenytoin toxicity, enhanced hypoglycemia, bone marrow suppression, and severe hyponatremia, respectively. TMP–SMX can enhance warfarin-induced anticoagulation and ganciclovir-induced bone marrow suppression, and it can diminish cyclosporine concentrations, resulting in a transplant rejection. Neutropenia and thrombocytopenia can occur in renal allograft recipients who receive azathioprine and more than 3 weeks of treatment with TMP–SMX. When prescribed to patients receiving a potassium-sparing diuretic, TMP–SMX has caused hyperkalemia.

Quinupristin–dalfopristin is a potent inhibitor of CYP3A4, and it should be used with caution when patients are receiving drugs that are substrates of 3A4, such as cyclosporine, nifedipine, protease inhibitors, and statins.

DRUG MONITORING

Monitoring the adequacy of antibiotic treatment involves the physician critically assessing the patient's response on a regular basis, as determined by the resolution of both the systemic and local inflammatory response and, in part, measured by results obtained from laboratory studies, microbiology data, and radiologic exams. In general, antibiotic concentrations in blood are not routinely measured. Aminoglycoside antibiotics are an exception, however, because serum concentrations of these compounds are performed to ostensibly reduce the risk of nephrotoxicity and ototoxicity and to ensure appropriate therapeutic levels. Better outcomes for treating patients with gram-negative bacteremia are noted if peak levels of gentamicin and tobramycin exceed 5 μg/mL and peak amikacin concentrations exceed 20 μg/mL. Avoiding elevated aminoglycoside levels may result in decreased ototoxic and nephrotoxic effects. Serial audiometric testing to assess ototoxicity should be considered for those patients receiving long-term administration of aminoglycosides and vancomycin. Some practitioners also measure vancomycin troughs to assist their choice of dosage interval and drug amount, and appropriate levels may reduce the incidence of ototoxicity.

Outpatient parenteral antibiotic therapy

Outpatient parenteral antibiotic therapy is designed either to avoid hospitalization or to continue treatment initiated in the hospital and to provide therapy that is therapeutically equivalent to the inpatient setting, while enhancing the patient's quality of life and achieving significant cost savings. The decision to initiate outpatient parenteral antibiotic therapy is influenced by the following factors: availability of an adequate oral treatment; the patient's clinical status and acceptance of this form of treatment; the home environment and support systems; the potential for treatment plan compliance; the availability of competent, professional follow-up; and the reimbursement status. Outpatient parenteral antibiotic therapy has been a safe and effective form of treatment for patients with a wide array of

infectious diseases, and antibiotics such as ceftriaxone, vancomycin, daptomycin, ertapenem, and aminoglycosides lend themselves to outpatient parenteral antibiotic therapy because these compounds can be administered infrequently. In addition to antibiotic-related adverse events, outpatient intravenous antibiotic infusion poses the risk of vascular access-related complications, such as venous thrombosis and catheter-related bloodstream infections.

Switch (step-down) therapy

The availability of numerous safe and effective oral antimicrobials that are well absorbed and can be administered infrequently provides the opportunity for switch or step-down therapy. This approach, available to the patient who has stabilized and appears to be "turning the corner," as manifested by resolution of fever with improved appetite and strength as well as the reduction of the signs and symptoms caused by the infection, has been successfully used to treat patients with the most commonly identified community-acquired infections. Switch therapy frees the patient from the inconvenience, discomfort, and risks of intravenous access, results in considerable cost savings, and permits earlier hospital discharge. Switch therapy requires patient compliance with the medication and adequate intestinal absorption of the antimicrobial, coupled with the appropriate follow-up from the clinician.

ANTIBACTERIAL PROPHYLAXIS

Appropriately administered antibiotic prophylaxis is the standard of care for patients who undergo selective surgical procedures. The ideal prescribed agent should cause minimal untoward events, should not select for virulent organisms, achieves adequate local tissue levels, is relatively inexpensive, demonstrates inhibitory activity for the bacteria anticipated to cause postoperative infection, and should be infused (usually 30–60 minutes before the surgery begins) so that therapeutic concentrations are present prior to the initial operative incision (see Chapter 114, Surgical prophylaxis).

In addition to their indication for the prevention of postoperative infections, antibacterial agents have been effective for the prevention (primary/secondary) of a number of nonsurgical disorders, including rheumatic fever, syphilis, travelers' diarrhea, tuberculosis, invasive meningococcal disease, pertussis, diphtheria, plague, and recurrent cystitis in women. Although no definite studies have confirmed that antibiotic prophylaxis provides protection against the development of endocarditis during bacteremia-producing procedures, it is currently recommended that patients with certain cardiac conditions receive antibiotic prophylaxis when subjected to selective dental, respiratory tract, gastrointestinal tract, and genitourinary tract bacteremia-producing procedures (see Chapter 113, Nonsurgical antimicrobial prophylaxis, and Chapter 37, Endocarditis of natural and prosthetic valves: treatment and prophylaxis).

ANTIMICROBIAL FAILURE

When a patient is not responding to antimicrobial therapy, there is a temptation to administer an alternative compound with an extended spectrum of activity. This approach is often valid, particularly for the seriously ill patient. It is essential, however, for the clinician to establish an accurate diagnosis, because noninfectious disorders often masquerade as infection. For example, hypersensitivity to an insect bite, acute gout, a fixed drug reaction, Lyme disease, necrotizing fasciitis, and anaerobic myonecrosis can initially resemble traditional bacterial cellulitis; Charcot joint in the diabetic simulates osteomyelitis; pulmonary infarction, lung cancer, acute respiratory distress syndrome, aspiration of gastric contents, drug-induced pneumonitis, and congestive heart failure can imitate an infectious pneumonia; and vasculitis can resemble endocarditis. There should be consideration given to those factors that have the potential to impede successful antibiotic treatment (obstruction, necrotic tissue, undrained abscess, or an infected prosthetic device), the possibility of a polymicrobic infection, the development of drug resistance or a superinfection, or infection in a "privileged site," such as meningitis, endocarditis, or chronic bacterial prostatitis, disorders that require antimicrobials with unique penetration properties.

The clinician should also consider drug compliance and adequacy of drug dosage and recognize that selective infections, such as bacterial endocarditis, bacterial meningitis, and life-threatening infections in granulocytopenic hosts, require a bactericidal antibiotic. An additional factor that can impact antibiotic treatment for patients is the recognition that numerous patients self-prescribe antibiotics prior to their first encounter with physicians. This practice can alter

the anticipated microbiologic cause, the manifestations of the infection, and the clinical response of the infection.

In addition to antibiotics, survival of seriously ill, hospitalized infected patients often requires early institution of adjunctive treatments. Therapies that merit consideration include vigorous fluid administration (goal-directed therapy), cardiovascular support with a vasopressor or an inotropic agent, oxygen delivery via lung-protective ventilation, and CRRT.

INAPPROPRIATE ADMINISTRATION

There are no convincing scientific data to support the administration of antibiotics to otherwise healthy patients who experience rhinitis and nonbacterial pharyngitis, laryngitis, acute bronchitis, or acute sinusitis. These infections are predominantly self-limited viral disorders. Antibiotic administration to these patients will serve only to add to healthcare-related costs, promote the spread of antibiotic-resistant organisms, and place patients at risk of adverse drug reactions. Additional disorders for which antibiotics are not indicated include witnessed aspiration pneumonia, colonized noninfected wounds, and asymptomatic bacteriuria, unless the latter condition is identified in a pregnant woman.

Antibiotic therapy is not appropriate treatment for the patient with persistent unexplained fever. These patients merit a thorough evaluation, consisting of a comprehensive medical history and physical examination, complemented with the judicious application of laboratory and radiographic studies. Empiric administration of an antibiotic to the patient with protracted fever may serve to obscure and/or delay the correct diagnosis and result in untoward drug-induced events.

When making decisions regarding the administration of antibiotics, clinicians should be guided by accurate susceptibility data for those clinically significant isolates recovered from appropriately collected specimens, as well as expert consultation, and evidence-based medicine as published in the practice guidelines.

ACKNOWLEDGMENT

This chapter includes contributions from the late Richard A. Gleckman.

206. Antibacterial agents

Richard R. Watkins

The discoveries of penicillin by Fleming in 1928 and sulfonamides by Domagk in 1932 originated the modern era of effective antibacterial therapy. Since then, over a dozen different classes of antibacterial agents have been developed. This chapter describes the various antibacterial agents, emphasizing their mechanisms of action, clinical indications, and mechanisms of bacterial resistance (Table 206.1).

Table 206.1 Overview of antibacterial agents

PENICILLINS AND MONOBACTAMS

The core structure of the penicillins consists of a thiazolidine ring attached to a β-lactam ring and an R-group side chain. The thiazolidine–β-lactam ring provides antibacterial activity, while the side chain determines the antimicrobial spectrum and pharmacologic characteristics. Penicillins are bactericidal agents that inhibit penicillin-binding proteins (PBPs), which are involved in the synthesis of peptidoglycan. PBPs vary in their concentrations among bacteria and in their binding affinity for β-lactam antibiotics. This largely explains why β-lactam antibiotics differ in their efficacy and antibacterial spectrum. One type of PBP is β-lactamase, which hydrolyzes and inactivates the β-lactam ring. The penicillins may be conveniently grouped into the following classes: natural penicillins, penicillinase-resistant penicillins, aminopenicillins, and extended-spectrum penicillins. In addition, some of the penicillins have been combined with β-lactamase inhibitors including clavulanic acid, sulbactam, and tazobactam, which widen their antibacterial spectrum of activity.

The natural penicillins, penicillin G and penicillin V, are so named because they can be purified directly from cultures of the mold *Penicillium*. Penicillin G is unstable in acid and inactivated by gastric contents. It is administered by intramuscular, subcutaneous, intrathecal, or intravenous injection. Benzathine penicillin G, the treatment for primary, secondary, and latent syphilis, is slowly absorbed from tissue after intramuscular injection and detectable in serum for up to 30 days. However, levels are inadequate for treating neurosyphilis and intravenous formulations should be used. Most bacteria have developed resistance to the natural penicillins. Those that remain susceptible include *Streptococcus pyogenes*, viridans group streptococci, some enterococci, some *Streptococcus pneumoniae*, *Listeria monocytogenes*, *Neisseria meningitidis*, some *Haemophilus influenzae*, *Clostridium* (except *Clostridium difficile*), *Actinomyces israelii*, and *Leptospira*. Penicillin V is only available for oral use and treats most of the same organisms as penicillin G, although it is less active against *Haemophilus* and *Neisseria*. Nafcillin, a penicillinase-resistant penicillin, is active against methicillin-sensitive *Staphylococcus aureus*, penicillin-susceptible strains of *S. pneumoniae*, and most anaerobic gram-positive cocci. Importantly, nafcillin does not treat enterococcus and *Listeria*. Oral formulations of penicillinase-resistant penicillins include

dicloxacillin (which is frequently used for skin and soft-tissue infections [SSTIs]) and cloxacillin. The aminopenicillins, ampicillin and amoxicillin, have improved activity against enterococci compared to penicillin G. Amoxicillin is better orally absorbed than ampicillin, while the latter is effective in treating meningitis due to *L. monocytogenes*, *N. meningitidis*, and group B streptococci. Ampicillin has been combined with the β-lactamase inhibitor sulbactam and is often given for mixed bacterial infections, such as intra-abdominal infections and obstetric and gynecologic infections. Amoxicillin–clavulanate is an oral formulation that is also given when multiple organisms need to be treated, such as animal or human bite wounds. The extended-spectrum penicillins include piperacillin, ticarcillin, and carbenicillin. Piperacillin is almost always given in combination with the β-lactamase inhibitor tazobactam. It has a wide range of activity including streptococci, anaerobes, enterococci, many Enterobacteriaceae as well as *Pseudomonas aeruginosa*. Piperacillin–tazobactam is utilized for many serious infections including hospital-acquired pneumonia, neutropenic fever, polymicrobial SSTIs, intra-abdominal infections, complicated urinary tract infections (UTIs), and often empirically for sepsis. Of note, use of piperacillin–tazobactam has been identified as a risk factor for *Candida glabrata* and *Candida krusei* fungemia. Ticarcillin–clavulanate is another parenteral broad-spectrum agent with similar indications as piperacillin–tazobactam, although less active against enterococci.

Monobactams consist of a single β-lactam ring with side chains. Currently the only commercially available monobactam is aztreonam. Monobactams are active exclusively against gram-negative aerobic bacteria. Aztreonam is not absorbed from the gastrointestinal tract and is usually given by the intravenous route. It is the only β-lactam that can be given to patients with allergies to penicillin or other β-lactam antibiotics since there is no cross-reactivity between them. An inhaled formulation of aztreonam has been developed for chronic use in cystic fibrosis patients with endobronchial *P. aeruginosa* infection.

Bacteria employ a number of resistance mechanisms against the penicillins and monobactams. The most common is the production of β-lactamase, which covalently reacts with and lyses the β-lactam ring. Four different classes of β-lactamases have been identified, designated A through D. Other mechanisms include efflux pumps which push penicillin out across the bacterial outer membrane, porins which do not allow passage of penicillins into the cytoplasm, and production of low-affinity PBPs.

CEPHALOSPORINS

The second major group of β-lactams, cephalosporins, are widely used in clinical practice. Currently there are over 20 cephalosporins available worldwide. They are composed of a β-lactam ring fused to a six-member dihydrothiazine ring. This structure bestows more intrinsic resistance against β-lactamases compared to the five-member ring of penicillin. Cephalosporins are commonly classified according to generation, with agents in each generation having a similar antibacterial spectrum of activity. Successive generations gain activity against aerobic gram-negative bacteria. Enterococci are intrinsically resistant to cephalosporins, although the new methicillin-resistant *S. aureus* (MRSA)-active cephalosporins have lower minimum inhibitory concentrations (MICs) against ampicillin-sensitive strains. The mechanism of action of cephalosporins is similar to other β-lactam agents, namely binding to and inhibiting PBPs, which in turn prevents peptidoglycan synthesis. Cephalosporins are bactericidal drugs and cause persistent suppression of bacterial growth for several hours, called post-antibiotic effect (PAE), in gram-positive bacteria, but not in gram-negative organisms. Their rapidity of bacterial killing is determined by the amount of time that the drug concentration exceeds the MIC, with maximal killing at four times the MIC.

The first-generation cephalosporins include cefazolin, cefadroxil, and cephalexin with the first administered parenterally and the latter two orally. Cefazolin is commonly used for infections caused by methicillin-sensitive staphylococci and streptococci, such as SSTIs, endocarditis from susceptible strains, and surgical prophylaxis for foreign-body insertion and other clean and clean-contaminated surgical procedures with a high risk for infection. The oral first-generation agents have good oral bioavailability and are effective for many SSTIs. They are often used to transition to oral therapy after parenteral cefazolin or in the outpatient setting. They are not active against *H. influenzae* or *Moraxella catarrhalis* and should not be used for respiratory infections. Second-generation cephalosporins are divided into two groups, the true cephalosporins (cefuroxime) and the cephamycins (cefoxitin and cefotetan). Cefuroxime was frequently used in the

past for respiratory tract infections, but its poor activity against penicillin-resistant *S. pneumoniae* has now limited its effectiveness. The cephamycins have good activity against aerobic gram-negative and anaerobic organisms and are first-line agents for intra-abdominal, gynecologic, and mixed skin infections. The parenteral third-generation cephalosporins (ceftriaxone, cefotaxime, ceftazidime, and ceftizoxime) have a number of important clinical indications. Ceftriaxone and cefotaxime are active against penicillin-resistant pneumococcus and are recommended for treatment of community-acquired pneumonia (combined with azithromycin) and meningitis. Ceftriaxone is the drug of choice for gonococcal infections and is combined with doxycycline to treat pelvic inflammatory disease. Both ceftriaxone and cefotaxime are active against *Borrelia burgdorferi* and are effective for neurologic Lyme disease. Also, these agents have good activity against Enterobacteriaceae, although caution should be used with monotherapy against *Citrobacter*, *Serratia*, and *Enterobacter* species as they can develop inducible resistance through chromosomal β-lactamase production. Ceftazidime has excellent activity against *P. aeruginosa* but limited activity against *S. aureus*. Several oral third-generation cephalosporins are available (cefpodoxime, cefixime, cefdinir, and cefditoren) and are commonly prescribed for respiratory infections, sinusitis, and otitis media. Currently the only available fourth-generation cephalosporin in the United States is cefepime. This drug has an enhanced spectrum of activity against gram-negative organisms including those with reduced sensitivity to third-generation drugs. Cefepime is recommended as monotherapy for patients with neutropenic fever, although it is often combined with an aminoglycoside. Ceftaroline and ceftobiprole are advanced-generation cephalosporins with broad gram-positive and gram-negative in vitro activity and comparable efficacy to vancomycin against MRSA. They are also active against ampicillin-sensitive enterococci but not against *P. aeruginosa* or *Acinetobacter* species. Ceftaroline has been approved in the United States to treat community-acquired pneumonia and SSTIs, including those caused by methicillin-sensitive and -resistant *S. aureus*.

CARBAPENEMS

Among the most broad-spectrum antibiotics, carbapenems are often reserved for serious infections. There are four available agents in this class: ertapenem, meropenem, imipenem, and doripenem. Their chemical structure is slightly different from other β-lactams in that the sulfur is replaced by a methylene group and the ring contains a double bond. Imipenem is a substrate for the kidney enzyme dehydropeptidase-1. It is coadministered with cilastin, a dehydropeptidase-1 inhibitor. Carbapenems have a similar mechanism of action, i.e., binding to high-molecular-weight PBPs, and are not hydrolyzed by most penicillinases. All have excellent activity against many gram-positive cocci. Penicillin-susceptible *Enterococcus faecalis* is susceptible to imipenem with MICs less than or equal to 2 μg/mL but resistant to the other carbapenems. *Enterococcus faecium* is resistant to all carbapenems, as are methicillin-resistant staphylococci. *Neisseria* species, *Haemophilus* species, and Enterobacteriaceae are all highly susceptible to carbapenems. Doripenem is the most active against *P. aeruginosa*, while ertapenem is inactive. Ertapenem also has poor activity against *Acinetobacter*. *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are intrinsically resistant to all four carbapenems. As a class, carbapenems are highly active against anaerobic bacteria.

Because of their activity against many gram-positive, gram-negative, and anaerobic bacteria, carbapenems treat a wide range of infections. Moreover, they are often a good choice for patients who have recently received other antibiotics or for empiric coverage of severe sepsis. From an antibiotic stewardship perspective, carbapenems are advantageous since they can replace multiple antibiotics with one drug. For instance, ertapenem, with its long half-life that permits once-daily dosing, is often given to treat polymicrobial infections. However, the convenience of carbapenems must be carefully balanced against the potential for the emergence of resistance. Adverse events are similar to other β-lactams, although as a class there is an increased risk for seizures, particularly with imipenem.

Resistance to carbapenems usually occurs through overproduction of efflux pumps, altering PBPs, diminished outer membrane permeability, or production of β-lactamases. Several species of Enterobacteriaceae carry the plasmid-borne carbapenemases KPC-1, KPC-2, and KPC-3 which are capable of degrading carbapenems. *P. aeruginosa* also has a distinct efflux pump that is capable of removing numerous antibiotics, including meropenem, doripenem, and ertapenem but not imipenem. The recently emerged carbapenemase NDM-1 (New Delhi metallo-β-lactamase-1) has

quickly spread worldwide. It is a class B carbapenemase (also called a metallolactamase) that requires zinc at its active site.

AMINOGLYCOSIDES

The first aminoglycoside to be produced was streptomycin in 1944. It was followed by neomycin, then gentamicin, tobramycin, and lastly amikacin in 1972. They are bactericidal agents that exhibit concentration-dependent killing. Aminoglycosides bind to the 30S subunit of the prokaryotic ribosome, preventing protein synthesis from mRNA. This occurs through penetration of the bacterial cytoplasmic membrane by an oxygen-dependent active transport mechanism. Because of this action, aminoglycosides work poorly in anaerobic environments such as abscesses. These agents demonstrate a significant PAE, which increases with the peak serum concentration. Aminoglycosides are rarely used as single agents and are usually combined with another antimicrobial, such as a β-lactam or vancomycin. This helps prevent the emergence of resistance and gains the benefit of synergy. In cases of endocarditis, gentamicin should be administered using multiple daily dosing. However, for other types of infections there are several advantages of once-daily administration over multiple daily dosing. Animal studies have shown a lower rate of drug-related toxicities as well as a more robust PAE with once-daily dosing. Studies in humans have also demonstrated that once-daily dosing is efficacious, causes less nephrotoxicity, and is more cost-effective compared to multiple daily dosing regimens. The toxicities of aminoglycosides are well established and include nephrotoxicity (incidence 5%–10%), ototoxicity, vestibular toxicity, and neuromuscular blockade. Therefore, these agents should be used cautiously in patients with myasthenia gravis, electrolyte abnormalities such as hypocalcemia and hypomagnesemia, or with concurrent drugs that interfere with neuromuscular transmission, such as calcium channel blockers. Renal failure associated with aminoglycosides is usually reversible and often resolves once the drug is discontinued. Ototoxicity is more likely to be permanent.

Among their clinical indications, aminoglycosides have in vitro activity against strains of methicillin-susceptible *S. aureus* (MSSA), although resistance can develop quickly unless used in combination with another active drug. Gentamicin is active against species of *Enterococcus*, but tobramycin and amikacin are not. Pneumococci and all other streptococci are resistant to aminoglycosides, as are anaerobic bacteria. Certain aminoglycosides have activity against mycobacteria, for instance streptomycin inhibits *Mycobacteria tuberculosis* and amikacin inhibits *Mycobacteria avium-intracellulare*. Most species of Enterobacteriaceae, *P. aeruginosa*, *Serratia*, and *Acinetobacter* remain susceptible to amikacin, gentamicin, and tobramycin but resistance rates vary between institutions. Of note, *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are resistant to these drugs. Streptomycin is effective therapy for *Yersinia pestis* and *Francisella tularensis*, and gentamicin plus doxycycline is used to treat brucellosis.

Overall, the prevalence of bacterial resistance to the aminoglycosides remains low. There are three main mechanisms for resistance to these agents: (1) point mutations in 16S ribosomal RNA; (2) efflux pumps that prevent accumulation of the drug; and (3) bacterial enzymes that modify the drug to bind poorly to ribosomes. Enterococci are intrinsically resistant due to their facultative anaerobic metabolism. Additionally, extended-spectrum β-lactamases (ESBL) are on plasmids that carry multiclass resistance genes including for aminoglycosides.

QUINOLONES

The first quinolone, nalidixic acid, was generated as a by-product during the production of chloroquine. Investigators discovered it had activity against certain gram-negative bacteria. Modifications of the compound including the addition of fluorine led to further quinolones with aerobic gram-positive, additional aerobic gram-negative, and some anaerobic activity. The most commonly used quinolones include ciprofloxacin, levofloxacin, ofloxacin, moxifloxacin, and gemifloxacin. They are rapidly bactericidal agents that stop bacterial DNA synthesis by inhibiting two enzymes, topoisomerase IV and DNA gyrase. Like aminoglycosides, quinolones cause PAE against gram-negative bacilli, lasting approximately 2 to 6 hours. The bioavailability of quinolones is high (close to 100%), making for an easy transition from the intravenous to oral route. They have a high distribution in tissues including lung, bile, prostate, and stool. Except for moxifloxacin, concentrations in the kidney and urine are high. Although bone concentration is less than serum, quinolones have been successfully used to treat osteomyelitis and prosthetic joint infections, especially when combined with rifampin in the latter.

Table 206.2 Characteristics of quinolones

Drug	Principle route of metabolism	Common clinical indications and uses
Ciprofloxacin	Renal	UTIs, prostatitis, atypical pneumonia, HAP, travelers' diarrhea, gastroenteritis, peritonitis prophylaxis with cirrhosis, chronic osteomyelitis; excellent activity against gram negatives including *P. aeruginosa*
Levofloxacin	Renal	AECOPD, CAP, HAP, *P. aeruginosa* infections
Moxifloxacin	Hepatic	Aspiration pneumonia, AECOPD, CAP, abdominal infections, mixed anaerobic infections
Ofloxacin	Renal	UTIs, prostatitis, travelers' diarrhea
Gemifloxacin	Renal	AECOPD, CAP

Abbreviations: UTI = urinary tract infection; CAP = community-acquired pneumonia; HAP = hospital-acquired pneumonia; AECOPD = acute exacerbations of chronic obstructive pulmonary disease.

The clinical uses for quinolones are presented in Table 206.2. Common toxicities associated with this class include gastrointestinal upset, dizziness, delirium (especially in the elderly), and rashes, while prolongation of the QT interval, arrhythmias, and tendonitis are rare but potentially serious. They should not be given with dairy products or metals like aluminum, calcium, or magnesium as these can reduce absorption of the drugs. Likewise, caution should be used in patients concurrently on warfarin, with close monitoring of prothrombin times as an increased risk of bleeding has been reported.

Bacterial resistance to quinolones occurs mainly from spontaneous mutations in genes that code for DNA gyrase or topoisomerase IV. Less commonly, resistance mutations occur in genes that encode membrane porin channels, leading to reduced diffusion, as well as overexpression of efflux pumps. Studies have shown an increased risk for the development of resistance while on therapy in *P. aeruginosa* and *S. aureus*.

TETRACYCLINES

Originally derived from soil microorganisms, tetracyclines have broad-spectrum activity against gram-positive and gram-negative bacteria, intracellular bacteria, and some parasites. They are bacteriostatic agents, have anti-inflammatory properties, and inhibit protein synthesis by binding to the 30S subunit of the bacterial ribosome. Currently there are three tetracyclines available for clinical usage: doxycycline, minocycline, and tetracycline. A similar class is the glycylcyclines, which are derivatives of minocycline and have a modified side chain at position 9. Tigecycline is currently the only available glycylcycline. Both doxycycline and minocycline have high bioavailability, while the bioavailability of tetracycline is reduced when taken with food. Like quinolones, their absorption is decreased by multivalent cations like calcium and magnesium. The routes of elimination differ between the agents, with tetracycline cleared through the urine, doxycycline through the feces, minocycline through the liver, and tigecycline through the biliary/fecal route and to a lesser extent the urine. Toxicities are uncommon and include gastrointestinal upset, esophageal ulcers, rashes, and photosensitivity reactions. Minocycline can cause vertigo, more often in women. Tetracyclines should be avoided in pregnant women and children under age 8 because of teeth staining. Patients should be encouraged to take oral tetracyclines with a full glass of water and remain upright for at least 30 minutes to decrease the risk for esophageal irritation.

Tetracyclines have a multitude of clinical uses. Doxycycline is included in the Infectious Diseases Society of America guidelines for the management of community-acquired pneumonia for monotherapy in outpatients and in combination with a β-lactam for inpatients. Given recent reports associating arrhythmias with macrolides and quinolones, doxycycline seems to be a safe and effective alternative. It is often used to treat mild MRSA SSTIs. Moreover, doxycycline has been associated with a lower risk for *C. difficile* infection than other antibiotics. Tetracyclines are first-line therapy for Lyme disease, Rocky Mountain spotted fever, Q fever, cat scratch disease, anaplasmosis, ehrlichiosis, bartonellosis, brucellosis, pelvic ulcer disease, and in combination therapy for *Helicobacter pylori*. They also serve as alternative therapy for several conditions when patients are allergic or otherwise intolerant to first-line agents, including syphilis, leptospirosis, and Whipple's disease. Tigecycline is a broad-spectrum antibiotic with activity against MRSA, vancomycin-resistant enterococci (VRE), and many gram-negative bacilli including multidrug-resistant strains of *Acinetobacter*. However, it does not treat "the three P's" *Pseudomonas*, *Proteus*, and *Providencia*, or *Morganella*. Tigecycline is indicated to treat intra-abdominal

Table 206.3 Characteristics of macrolides

Drug	Mechanism of action	Common clinical uses	Adverse reactions
Erythromycin	Binds bacterial 50S ribosome and inhibits RNA-dependent protein synthesis	*Bordetella pertussis* Atypical respiratory pathogens Prokinetic agent for gastroparesis	Nausea, vomiting, rashes, ototoxicity (high doses), QT prolongation
Azithromycin	Binds bacterial 50S ribosome and inhibits RNA-dependent protein synthesis	Pharyngitis Bacterial sinusitis CAP Otitis media MAC treatment and prophylaxis NGU Q fever SSTIs	Diarrhea, nausea, abdominal pain, cholestatic hepatitis, arrhythmias
Clarithromycin	Binds bacterial 50S ribosome and inhibits RNA-dependent protein synthesis	Pharyngitis Bacterial sinusitis CAP Otitis media *H. pylori* MAC and other mycobacterial infections (except MTb) Q fever SSTIs	Diarrhea, nausea, abdominal pain, arrhythmias
Fidaxomicin	Inhibits bacterial RNA polymerase	*C. difficile* infection; lower relapse rate compared to vancomycin except with NAP1/B1/027 strain	Nausea, vomiting, abdominal pain, gastrointestinal hemorrhage

Abbreviations: CAP = community-acquired pneumonia; MAC = *Mycobacterium avium* complex; MTb = *Mycobacterium tuberculosis*; NGU = nongonococcal urethritis; SSTIs = skin and soft-tissue infections.

infections, community-acquired pneumonia, and SSTIs. Approximately 25% of patients develop nausea, which may necessitate discontinuation of therapy.

Tetracycline resistance occurs mainly by acquisition of exogenous genes for efflux pumps and ribosomal protection proteins. Tigecycline has a higher affinity for ribosomes and can overcome ribosomal protection proteins, although it remains susceptible to multidrug-resistance pumps.

MACROLIDES

The macrolide group of antibiotics includes erythromycin, azithromycin, clarithromycin, and the new agent fidaxomicin (previously OPT-80), which was approved by the US food and Drug Administration (FDA) in May 2011. The first three drugs are used to treat a wide range of infections, while fidaxomicin is only used to treat *C. difficile* (Table 206.3). In addition to their primary indications, macrolides are often used as alternative agents for several conditions, such as Lyme disease in pregnancy and streptococcal pharyngitis in penicillin-allergic patients.

The first macrolide to be discovered, erythromycin, previously had good activity against many gram-positive organisms, but resistance has decreased its clinical efficacy. Erythromycin still maintains excellent activity against *Bordetella pertussis* and atypical respiratory pathogens. It is also used as a prokinetic agent for gastroparesis. However, gastrointestinal side effects and frequent dosing limit its use. Azithromycin has been the most commonly prescribed antibiotic in the United States for adults in recent years. It is better tolerated than erythromycin and, for many of its indications, is taken once a day for a 5-day course. Unfortunately, azithromycin has been associated with an increased risk of cardiovascular death, estimated at 47 additional cardiovascular deaths per 1 million courses.

All macrolides exhibit anti-inflammatory and immunomodulatory properties. Evidence suggests they are beneficial in certain chronic noninfectious illnesses such as cystic fibrosis and bronchiectasis. Their role in cardiovascular disease is controversial and requires further clarification.

Resistance to erythromycin, azithromycin, and clarithromycin is mediated through efflux pumps, mutations in genes for 50S ribosomal

proteins, and enzymatic inactivation by phosphotransferases. A single strain of *C. difficile* with an elevated fidaxomicin MIC taken from a cured patient was found to have a single mutation in the β subunit of the RNA polymerase.

GLYCOPEPTIDES, LIPOPEPTIDES, AND STREPTOGRAMINS

Vancomycin, derived from the word "vanquish," was the first glycopeptide introduced for clinical use. The other glycopeptide is teicoplanin, which is available in Europe and Asia but not the United States. Glycopeptides are bactericidal agents that inhibit cell wall synthesis in dividing bacteria by binding to precursors of the peptidoglycan chain. Vancomycin has activity against most strains of staphylococci (including MRSA), streptococci, and enterococcus. Most strains of *L. monocytogenes* are susceptible although some with high MICs have been reported. *Leuconostoc*, *Lactobacillus*, and *Pediococcus* are intrinsically resistant. Vancomycin is used for many serious infections including meningitis, endocarditis, MRSA pneumonia, cellulitis, osteomyelitis, and gram-positive bacteremia. Oral vancomycin, which is not systemically absorbed, is used to treat moderate to severe *C. difficile* infections and recurrences. Adverse reactions to the drug are uncommon and include infusion-related reactions such as rash (red man syndrome), neutropenia, thrombocytopenia, ototoxicity, and nephrotoxicity. Resistance in enterococci is mediated by the *van* genes, which are found mostly in *E. faecalis* and can be transmitted to other bacteria such as staphylococci. It is increasingly common for strains of *S. aureus* to exhibit rising MICs to vancomycin (so-called "MIC creep"). Indeed, high rates of clinical failure with vancomycin have been observed with MRSA bacteremia when the vancomycin MIC is 2 μg/mL or greater.

Telavancin is a semisynthetic lipoglycopeptide derived from vancomycin. It has a bactericidal concentration-dependent method of killing and a dual mechanism of action, inhibiting cell wall synthesis and disrupting membrane integrity. Telavancin exhibits potent in vitro activity against many gram-positive organisms, including staphylococcus, streptococcus, both vancomycin-susceptible and -resistant enterococcus, and gram-positive anaerobes. In the United States, telavancin is approved for the treatment of patients with complicated SSTIs. Women of childbearing age should have a pregnancy test prior to starting telavancin because of possible teratogenicity. Dalbavancin is another lipoglycopeptide with broad gram-positive activity, recently approved for skin and skin structure infections. It has a long half-life and is given once weekly for two doses.

The lipopeptide daptomycin is a rapidly acting, bactericidal agent that forms calcium-dependent ion channels in the cytoplasmic membrane of gram-positive organisms, causing loss of intracellular potassium and cell death. Daptomycin has a similar spectrum of activity as vancomycin and can be used to treat SSTIs, *S. aureus* bloodstream infections and right-sided endocarditis, osteomyelitis, and septic arthritis. Pulmonary surfactant inactivates daptomycin and it should not be used for pneumonia. It is usually well tolerated but reversible myopathy can occur. Therefore, monitoring of creatine phosphokinase (CPK) should be done weekly and concurrent statin therapy should be avoided. Resistance to daptomycin has been associated with MRSA strains with decreased susceptibility to vancomycin. Many bacteria with elevated daptomycin MICs demonstrate phenotypic changes in their cell membranes.

The streptogramins consist of two different macrocyclic compounds that each bind to the 50S subunit of the bacterial ribosome, inhibiting protein synthesis. Currently quinupristin–dalfopristin is the only streptogramin available in the United States. It is active against most gram-positive organisms (except *E. faecalis*) and a few gram-negatives including *Neisseria gonorrheae*, *N. meningitidis*, *M. catarrhalis*, and *H. influenzae*. Resistance occurs through conformational changes in the 50S subunit, enzymatic inactivation, and production of efflux pumps. The clinical use of quinupristin–dalfopristin has been limited by its frequent side-effects (arthralgias, myalgias, hyperbilirubinemia), many drug interactions, and because it needs to be administered through a central line due to frequent thrombophlebitis and pain when given peripherally.

OXAZOLIDINONES

Linezolid is the first of the oxazolidinones, a completely synthetic class of antibacterial agents with broad gram-positive activity. Unlike vancomycin, daptomycin, and quinupristin–dalfopristin, linezolid is available in both intravenous and oral formulations. It is a bacteriostatic agent that inhibits protein synthesis by binding to 23S rRNA in the catalytic site of the 50S ribosome. It is

approved for the following indications: (1) VRE infections, including bacteremia; (2) nosocomial pneumonia caused by MSSA, MRSA, and *Streptococcus pneumoniae*; (3) complicated skin and skin structure infections, including diabetic foot infections without concurrent osteomyelitis, caused by MSSA, MRSA, *Streptococcus pyogenes*, or *Streptococcus agalactiae*; (4) uncomplicated skin and skin structure infections caused by MSSA or *S. pyogenes*; (5) community-acquired pneumonia caused by MSSA or *S. pneumoniae*. Adverse events are uncommon and usually mild, including headache, nausea, and diarrhea. More serious ones can also occur, usually if linezolid is given for greater than 28 days. These include anemia, thrombocytopenia, lactic acidosis, optic neuritis, and peripheral neuropathy. It is therefore recommended that a weekly complete blood count be done while on therapy. Linezolid can cause serotonin syndrome when taken concurrently with selective serotonin reuptake inhibitors (SSRIs) and should be avoided. Resistance to linezolid has been observed in strains of MRSA and VRE with mutations in the 23S ribosomal RNA domain V region and is usually associated with prior exposure to the drug. Once-daily tedizolid phosphate has recently been approved, and other oxazolidinones are in various stages of development.

SULFONAMIDES

The first class of antibacterials in clinical use, sulfonamides are still widely prescribed. There are two agents currently available: trimethoprim–sulfamethoxazole (TMP–SMX) and dapsone. They are bacteriostatic and inhibit folic acid synthesis, stopping bacterial growth. Trimethoprim is a dihydrofolate reductase inhibitor that potentiates the activity of sulfonamides but also has antibacterial properties itself. Sulfonamides have broad in vitro activity against many gram-positive and gram-negative bacteria. TMP–SMX is most often used to treat UTIs, including pyelonephritis, cystitis, and prostatitis. It can also be given as prophylaxis for patients with recurrent UTIs. Furthermore, TMP–SMX is effective for treating SSTIs due to community-associated MRSA, with >90% of strains currently susceptible. It is first-line therapy for patients with *Pneumocystis jirovecii* pneumonia (PCP), as well as PCP prophylaxis. Intravenous TMP–SMX is often used in severe cases. Dapsone is the treatment of choice for leprosy and for PCP prophylaxis in patients intolerant of TMP–SMX. Hemolytic anemia can occur on dapsone especially in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency, so a G6PD level should be obtained before therapy is started. Adverse reactions associated with TMP–SMX include rashes (rarely Stevens–Johnson syndrome), fever, gastrointestinal upset, hepatitis, cytopenias, and hyperkalemia.

Because of long-standing usage (>70 years), widespread resistance to the sulfonamides has developed. It is mediated by overproduction of para-aminobenzoic acid (PABA) or structural changes in dihydropteroate synthetase, or by plasmids that code for the production of drug-resistant enzymes or decreased bacterial cell wall permeability.

METRONIDAZOLE AND CLINDAMYCIN

Developed in the 1950s, metronidazole is commonly used for parasitic and anaerobic infections. It is bactericidal and acts by interfering with electron transport proteins via reduction of its nitro group, leading to free radical formation and cell death. Oral metronidazole is well absorbed and serum levels are comparable to intravenous therapy. Metronidazole is active against nearly all gram-negative anaerobic bacteria, including *Bacteroides fragilis*, gram-positive anaerobes such as *C. difficile*, *H. pylori*, and parasites such as *Giardia*, *Entamoeba*, and *Trichomonas vaginalis*. Clinically it is used to treat a variety of anaerobic infections such as brain abscesses, bacteremia, endocarditis, bacterial vaginosis, bone and joint infections, and infections of the head and neck. Oral metronidazole is effective against mild *C. difficile* infection, although recurrences are common (approximately 25%). Of note, it should not be used as a single agent in treating lung abscesses because of the frequent presence of aerobic gram-positive cocci, against which it lacks activity. Adverse reactions associated with metronidazole include gastrointestinal upset, rashes, neutropenia, neurologic complaints such as headache, dizziness, and peripheral neuropathy. Alcohol should be avoided as it can lead to a disulfiram-like reaction. Resistance is rare and results from a decreased capacity of the electron transport chain to reduce the nitro group of metronidazole. Certain strains of *H. pylori* acquire resistance from mutational inactivation of the *rdxA* gene.

Clindamycin is a chemical modification of lincomycin, the original member of the lincosamide group. Similar to the macrolides, clindamycin binds to the 50S subunit of the bacterial ribosome

and inhibits protein synthesis. It has in vitro activity against many aerobic gram-positive bacteria, including staphylococci and streptococci, and anaerobes, although resistance is becoming more common. In particular, approximately 25% of clinical strains of *B. fragilis* are resistant to the drug. Clindamycin is used to treat lung abscesses, intra-abdominal and gynecologic infections, and gas gangrene from *Clostridium perfringens*. Topical formulations are effective for acne vulgaris and vaginal ones for bacterial vaginosis. It has good activity against MSSA but less so with MRSA. A D test should be done on strains of MRSA or *S. pyogenes* resistant to erythromycin; a positive D test indicates resistance to clindamycin will also occur. It can also be given as an adjunctive agent to bind toxins produced by *S. pyogenes* and *S. aureus*. Finally, clindamycin can serve as an alternative to penicillin or macrolides for most indications for patients with drug allergies. The major toxicity associated with clindamycin is *C. difficile* infection, which is not infrequent and now limits its clinical usage. Resistance to the drug occurs mainly through 50S ribosomal modification and enzymatic inactivation.

RIFAMYCINS

A versatile class of drugs, the rifamycins have many indications but are usually used in combination with other antibiotics. There are four drugs currently available: rifampin, rifabutin, rifapentine, and rifaximin. Rifamycins act by inhibiting the β-subunit of bacterial RNA polymerase. They are potent inducers of the cytochrome P450 system. This leads to many drug interactions including human immunodeficiency virus (HIV) medications, warfarin, cardiovascular drugs such as beta-blockers and statins, and immunosuppressive agents such as tacrolimus and glucocorticoids. Rifamycins are also associated with many adverse reactions. They cause an orange-red discoloration of tears and other secretions. Gastrointestinal symptoms such as nausea, vomiting, and diarrhea are common, while rashes, hepatitis, cytopenias, uveitis, and a lupus-like syndrome can also occur.

There are different clinical indications for each of the rifamycins. Rifampin is the oldest and most commonly used. It can be given as an alternative to isoniazid for treatment of latent tuberculosis, as one of the four drugs to treat active tuberculosis, in combination with dapsone for leprosy, as monotherapy for prophylaxis against meningococcal disease, or in combination therapy for prosthetic valve endocarditis or osteomyelitis (especially with foreign bodies) from *Staphylococcus*. Furthermore, rifampin can be used to eradicate MRSA colonization along with another drug such as doxycycline. Rifabutin and rifapentine are mainly used to treat mycobacterial infections. Rifaximin is poorly absorbed and is indicated for travelers' diarrhea. Moreover, it is sometimes used for recurrent or refractory *C. difficile* infection, usually for 2 weeks after finishing a standard course of oral vancomycin. Rifaximin is also effective for treating and preventing hepatic encephalopathy.

Resistance to rifamycins occurs mainly through single-step mutations in the gene that codes for RNA polymerase. Because this process occurs rapidly, rifamycins are not used to treat infections by themselves, except for the few indications noted above.

POLYMYXINS

First discovered in the 1940s, polymyxins were used to treat serious gram-negative infections until around 1980, when safer agents with less nephrotoxicity became available. They have reemerged in recent years, often as agents of last resort, due to the ongoing spread of multidrug-resistant bacteria. The two drugs in this class currently available are polymyxin B and colistin. They are rapidly bactericidal and act like a detergent by punching holes in the bacterial cell membrane. Polymyxins have broad activity against aerobic gram-negative bacteria, including most strains of *P. aeruginosa* and *Acinetobacter baumannii*. However, *Proteus*, *Serratia*, *Providencia*, *Burkholderia*, *Moraxella*, *Vibrio*, *Morganella*, *Helicobacter*, and *Edwardsiella* are resistant. Colistin is often used parenterally to treat serious multidrug-resistant gram-negative bacterial infections such as ventilator-associated pneumonia. Aerosolized colistin is also available and mainly given to treat colonization or infection of the bronchial system in patients with cystic fibrosis. A dose-related nephrotoxicity is a common side effect and is usually reversible with discontinuation of the drug. Also, neurologic side effects can occur, such as paresthesias, peripheral neuropathy, and muscle weakness. Resistance to polymyxins develops through modification of lipopolysaccharides on the bacterial cell wall.

MISCELLANEOUS AGENTS

Chloramphenicol is rarely used in North America and Europe, although an inexpensive oral formulation is widely available in underdeveloped countries. It has excellent activity against aerobic gram-positive and gram-negative bacteria, anaerobes (including *Clostridium* and *B. fragilis*), and atypical bacteria. However, serious toxicities limit its clinical utility. Most common is reversible bone marrow suppression. Development of aplastic anemia from chloramphenicol is rarer but can be irreversible. Because of these, it should only be used for serious, life-threatening infections (e.g., bacterial meningitis) when alternative drugs are contraindicated.

Nitrofurantoin is an oral agent used to treat and prevent UTIs. It is bactericidal and acts by inhibiting translation and pyruvate metabolism. Over 90% of *Escherichia coli* and *Citrobacter* strains are susceptible, and it has excellent activity against group B streptococci, *Staphylococcus saphrophyticus*, and enterococci including VRE. However, most other strains of Enterobacteriaceae are resistant. For uncomplicated cystitis, a 10-day course of therapy is usually given as shorter courses have been associated with suboptimal cure rates. Daily nitrofurantoin (100 mg) is effective therapy for both young and postmenopausal women with asymptomatic and symptomatic bacteriuria. Toxicities include gastrointestinal symptoms, pulmonary reactions including fibrosis, hepatitis, hemolytic anemia, and peripheral neuropathy. Patients on long-term prophylaxis should be monitored for these conditions.

Pivmecillinam is a β-lactam antibiotic with activity against Enterobacteriaceae, including ESBL-producing strains. It is used to treat lower UTIs and is orally administered. The drug has good clinical efficacy but high rates of persistent bacteriuria have been found. Pivmecillinam is primarily used in Scandinavian countries and currently is not available in the United States.

Fosfomycin is another oral agent for lower UTIs whose usage has been increasing in recent years because of bacterial resistance to other agents. It is bactericidal and inhibits cell wall synthesis through inactivation of the bacterial enzyme MurA. Resistance occurs through mutations in the bacterial membrane transporter for the drug. Fosfomycin has broad-spectrum antibacterial activity. Among susceptible pathogens are *E. coli* (including ESBL-producing strains), *Citrobacter*, *Proteus*, and *Enterococcus* (including VRE). Rates of susceptibility vary in *Klebsiella* and *Enterobacter*, while strains of *Pseudomonas* are often resistant. Fosfomycin is given as a one time mega-dose that is formulated as a powder and dissolved in a glass of water. It can also be given as a prophylactic agent for recurrent UTIs once every 10 days.

TOPICALS

Topical antibiotics are important agents for both treating and preventing infections of the skin, as well as to eradicate chronic carriage of certain pathogens such as MRSA. The introduction of antisepsis techniques by Dr. Joseph Lister in the nineteenth century was a seminal event in medicine, and skin disinfection for surgery remains a crucial procedure to prevent infection. The two most common agents used for this purpose are povidone-iodine and chlorhexidine, with the latter becoming more widely available and popular in recent years.

Available topical antibacterials include silver sulfadiazine, which is mainly used as a burn wound dressing. Activated silver has broad-spectrum antimicrobial activity and some anti-inflammatory properties. Silver sulfadiazine decreases colonization of wounds but there is no clear evidence it treats infections or improves wound healing. Bacitracin is active against many gram-positive bacteria including staphylococci, streptococci, and clostridia. It is effective for treating impetigo but may also lead to slower wound healing. Mupirocin is another agent with in vitro activity against gram-positive organisms, especially MRSA. It is used to treat impetigo, folliculitis, infected wounds and ulcers, and to decolonize the nares in patients colonized with *S. aureus*. Unfortunately, the development of mupirocin resistance in MRSA is becoming increasingly common. Neomycin is an aminoglycoside with activity against both gram-positive and gram-negative organisms including *S. aureus*, *S. pyogenes*, *E. coli*, *Proteus*, and *Serratia* while *P. aeruginosa* is usually resistant. It can cause contact sensitivity and resistance may develop. Neomycin is not recommended for patients with decreased renal function as it can be systemically absorbed, leading to ototoxicity. Polymyxin B is bactericidal against several aerobic gram-negative organisms including *P. aeruginosa* but not species of *Proteus*, *Serratia*, and *Providencia*. It is often used in combination with another agent such as bacitracin. Fusidic acid is another topical with only gram-positive activity.

It gets good tissue penetration and is useful for treating boils. Retapamulin has in vitro activity against staphylococci (including MRSA) and streptococci and exhibits a potent post-antibiotic effect lasting 3 to 4 hours. It is indicated for treating impetigo in adults and children.

FUTURE DIRECTIONS

The spread of antibiotic-resistant bacteria presents a major challenge to public health in the twenty-first century. Indeed, some experts believe we will soon enter the post-antibiotic era. In order to forestall this dire prediction, judicious usage of antibiotics should be a salient intervention, as well as novel infection control methods that reduce the spread of multidrug-resistant pathogens. Ongoing efforts at drug development by the pharmaceutical industry should be actively supported by all relevant stakeholders, including payers, professional societies, and government agencies.

207. Antifungal therapy

Nathan P. Wiederhold and Thomas F. Patterson

This chapter focuses on the use of drugs that treat systemic mycoses (Table 207.1). Treatment of cutaneous fungal infections is discussed in Chapter 26, Superficial fungal diseases of the hair, skin, and nails.

AMPHOTERICIN B

Amphotericin B is a polyene antifungal synthesized by *Streptomyces nodosus*. Its chemical structure confers it with amphoteric properties that are essential for the drug's ability to form channels through the cytoplasmatic membrane. The pores formed from preferential binding of amphotericin B to ergosterol, the primary fungal cell sterol, result in an increase in membrane permeability, leading to a loss of essential elements such as potassium and other molecules that impairs fungal viability. Amphotericin B binds with less affinity to cholesterol, the primary cell sterol of mammalian cells, which are therefore less affected by amphotericin B than is the fungal target.

Amphotericin B is commercially available as a complex with sodium deoxycholate: commercial vials contain amphotericin B, 50 mg, sodium deoxycholate, 41 mg, and a sodium phosphate buffer, 25.2 mg. The clinical pharmacology of amphotericin B is characterized by extensive binding to plasma proteins (>95%) and wide distribution to the peripheral compartment with preferential accumulation in liver and spleen, with lesser amounts in kidney and lung. Intravenous administration of therapeutic doses results in peak plasma levels of 1.0 to 1.5 μg/mL falling to 0.5 to 1.0 μg/mL 24 hours later. At therapeutic doses, less than 5% of the drug is excreted in the urine. The elimination of amphotericin B is not altered in patients with renal or liver dysfunction and does not require dose adjustment in patients who are anephric or undergoing hemodialysis. Cerebrospinal fluid (CSF) levels are low, although higher concentrations occur in brain tissue. Amphotericin B also diffuses poorly into other body fluids such as saliva, amniotic fluid, aqueous humor, and vitreous humor. However, drug concentrations in inflamed pleura, peritoneum, aqueous humor, and joint spaces are roughly two-thirds of the trough plasma concentration.

For clinical administration, amphotericin B is diluted in 5% dextrose (at a concentration of ≤0.1 mg of amphotericin B per milliliter of diluent) and infused intravenously over 2 to 4 hours at dosages of 0.5 to 1.5 mg/kg/day. The most common side effects of amphotericin B treatment are acute infusion-related reaction and nephrotoxicity. The acute infusion-related reaction consists of a syndrome of chills/rigors, fever, and tachypnea that typically occurs 30 to 45 minutes after beginning the first infusion and may last for 2 to 4 hours. Premedication with acetaminophen (650 mg given orally or rectally), hydrocortisone (25 to 50 mg given intravenously or mixed with the amphotericin B infusion solution), and diphenhydramine (50 mg given orally or rectally) can diminish the frequency and severity of these reactions. Chills and rigors may be terminated by the administration of meperidine (50 mg given intravenously). The acute symptoms associated with amphotericin B infusion can be serious. The occurrence of severe infusion reactions is considered an indication for use of lipid-associated amphotericin B preparations, which are usually significantly better tolerated (see below).

The other major side effect of amphotericin B is the development of nephrotoxicity, which occurs through a decrease in the glomerular filtration rate as a result of a direct vasoconstrictive effect on afferent renal arterioles, reducing glomerular and renal tubular blood flow, and by direct effects on the distal tubules resulting in the loss of cations. The nephrotoxicity may be exacerbated by other nephrotoxic agents. There is evidence that renal vasoconstriction is partially reversible

Table 207.1 Antifungal agents: therapeutic options

	Therapy	
DISEASE	PRIMARY	ALTERNATIVE
Aspergillosis: invasive	Voriconazole 6 mg/kg IV q12h for 2 doses then 4 mg/kg or 200–300 mg PO q12h	Liposomal formulations of AmB (see Table 207.3 for dosage) Caspofungin 70 mg IV × 1 dose, then 50 mg IV/d AmB, 1.0–1.5 mg/kg/d IV Posaconazole 300 mg BID on day 1 then 300 mg QD (tablet and IV); 800 mg/d in 2–4 doses (oral suspension) Itraconazole 400 mg/d PO (oral solution preferred)
Blastomycosis	Itraconazole, 200–400 mg/d PO for 6 mo; or AmB or L-AmB	Fluconazole, 400–800 mg/d for at least 6 mo
Candidiasis		
Candidemia	Caspofungin, 70 mg IV × 1 dose then 50 mg IV/d, or micafungin, 100 mg IV/d, or anidulafungin, 200 mg IV × 1 dose then 100 mg IV/d, followed by fluconazole 400–800 mg/d IV/PO (for susceptible organisms) or voriconazole when clinically stable to complete 14-d course after last positive blood culture If neutropenic, longer courses – until neutropenia resolves – may be necessary	Fluconazole 400–800 mg/d IV/PO for less seriously ill In patients who fail to respond or deteriorate, lipid formulations may be necessary Avoid fluconazole in patients with recent azole exposure, or if *Candida krusei* likely
Hepatosplenic candidiasis	L-AmB 3–5 mg/kg/d or Fluconazole, 800 mg/d IV	AmB lipid complex (ABLC), 5 mg/kg/d
Coccidiomycosis		
Nonmeningeal (AIDS and non-AIDS)	Fluconazole, 400–800 mg/d PO for 12–18 mo	Itraconazole, 200 mg BID PO × 12–18 mo, or AmB, 0.6–1.0 kg/d IV; total dose, ≥2.5 g In HIV, suppressive treatment with fluconazole, 200–400 mg/d PO, or itraconazole, 200–400 mg/d PO Posaconazole, voriconazole investigational
Meningeal (AIDS and non-AIDS)	Fluconazole, 400–800 mg/d PO indefinitely	L-AmB/AmB IV as for nonmeningeal Posaconazole, voriconazole investigational
Cryptococcosis		
Nonmeningeal	AmB, 0.7 mg/kg/d IV ± 5-FC 25 mg/kg PO q6h until response, then fluconazole, 400 mg/d PO for 8–10 wk, or Lipid AmB 3–5 mg/kg/d IV ± 5-FC as above	Fluconazole 400–800 mg/d IV Posaconazole, voriconazole investigational
Meningeal	AmB, 0.7 mg/kg/d IV ± 5-FC, 25 mg/kg PO q6h for 2 wk, then fluconazole, 400 mg/d PO for 8–10 wk, or fluconazole, 400 mg/d PO for 8–10 wk (for less severely ill patients)	Oral fluconazole less favorable success rates; Posaconazole, voriconazole investigational
Histoplasmosis		
Non-AIDS	Itraconazole, 400 mg/d PO for 9 mo; if life threatening, AmB, 0.7–1.0 mg/kg/d or lipid AmB 3–5 mg/kg/d IV × 14 d, followed by itraconazole, 400 mg/d × 8–10 wk if clinical response	
Disseminated/ AIDS	AmB, 0.7–1.0 mg/kg/d IV or lipid AmB 3–5 mg/kg/d × 14 d, followed by itraconazole, 400 mg/d × 8–10 wk, then begin suppressive treatment with itraconazole 200 mg/d PO	Itraconazole, 300 mg BID PO × 3 d, then 200 mg BID PO × 12 wk, or 400 mg/d × 12 wk, then 200 mg/d PO (less seriously ill)
Mucormycosis	Surgery plus lipid AmB 5–7.5 mg/kg/d IV	Posaconazole, AmB 0.8–1.5 mg/kg/d IV
Sporotrichosis		
Lymphocutaneous	Itraconazole, 200 mg/d PO × 6 mo	Potassium iodide solution (SSKI), 10–15 gtt TID × 6–12 wk
Extracutaneous	AmB or L-AmB (may require adjunctive intra-articular therapy or surgery)	Itraconazole, 200–300 mg PO BID × 6 mo, then 200 mg PO BID long term

Note: Dosages and duration of therapy given are approximations based on clinical response and underlying condition in the host. Individual responses and therapeutic requirements may vary.

Abbreviations: AmB = amphotericin B; 5-FC = flucytosine; AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus.

by salt loading with 500 to 1000 mL of normal saline before each infusion. Other renal effects include potassium and bicarbonate wasting and decreased erythropoietin production. Permanent loss of renal function can occur if the drug is continued in the setting of worsening renal function. Other chronic toxicities include nausea and vomiting, anorexia, normocytic normochronic

anemia (with the hematocrit rarely falling below 20% to 25%), and, rarely, thrombocytopenia, leukopenia, and peripheral vein phlebitis.

Amphotericin B is active against most fungal pathogens that cause systemic or deep-seated infections. Despite its significant dose-limiting toxicities, amphotericin B remains an option for many mycoses because of its broad spectrum of activity and fungicidal activity, although the availability of better tolerated and effective alternative agents (including lipid formulations of amphotericin B, the extended-spectrum azoles, or the echinocandins) have limited indications for the use of amphotericin B deoxycholate. Recommendations for appropriate dosages of amphotericin B and for duration of therapy remain poorly defined for most infections. In the past, total doses of 1 to 2 g for serious infections (which is approximately 15 to 30 mg/kg over a 6-week period) were usually recommended. However, the dosage and duration of amphotericin B depend largely on response of infection to therapy and resolution of underlying host immunodeficiency (e.g., resolution of neutropenia). Increasingly, a therapeutic approach that includes aggressive "induction" courses of amphotericin B followed by "consolidation" therapy with an azole, which can be administered orally, is used. This strategy has been evaluated most thoroughly in cryptococcal meningitis, but clinical reports have documented success of sequential amphotericin B to azole therapy in candidemia (using oral fluconazole), invasive aspergillosis (with an oral anti-*Aspergillus* azole such as voriconazole, posaconazole, or itraconazole), and endemic fungi (coccidioidomycosis and histoplasmosis with fluconazole and itraconazole, respectively). Generally, a 2-week (or until signs of infection have resolved or significantly improved) course of amphotericin B can be followed by azole therapy although none of the azoles are licensed for use in that manner.

Local instillation is rarely indicated due to the advances in alternative agents. Historically, itrathecal amphotericin B was a mainstay of therapy for coccidioidal meningitis, but the use of intrathecal amphotericin B is associated with substantial toxicity; consequently, that approach is now usually reserved for patients in whom systemic therapy fails, including high dosages of an azole. In other cases, local instillation of amphotericin B into the bladder via a Foley catheter has been used for urinary tract candidiasis, but systemic azole therapy, usually with fluconazole, is well tolerated and effective for that indication.

Lipid preparations of amphotericin B have been developed in an attempt to reduce the nephrotoxicity of the conventional form of amphotericin B deoxycholate. The administration of such liposomal forms modifies the pharmacokinetic and toxicologic properties of amphotericin B and as such these preparations have largely replaced amphotericin B deoxycholate for recommended use in serious fungal infections. Characteristics of the commercially available lipid amphotericin B preparations, liposomal amphotericin B (L-AMB, AmBisome), amphotericin B lipid complex (ABLC, Abelcet), and amphotericin B colloidal dispersion (ABCD, Amphotec), are shown in Table 207.2, although the use of ABCD is limited due to the increased toxicity associated with that formulation. Serum levels of L-AMB are higher than those achieved with standard amphotericin B, but serum levels of ABLC and ABCD are similar to those of amphotericin B deoxycholate. The advantage of the administration of amphotericin B in lipid complexes or in liposomes is the reduced rate of nephrotoxicity, allowing the delivery of larger amounts of the drug. Although few direct comparisons of the preparations have been performed, the fewest infusion reactions appear to occur with L-AMB with slightly more reactions, including chills and fevers, associated with ABLC. The highest incidence of infusion-related toxicities, including hypoxia, has been reported with ABCD. Infusions of L-AMB have been associated with anxiety, nervousness, restlessness, and chest pain, which have been described as a feeling of impending doom.

The lipid amphotericin B formulations have shown efficacy in many indications, including their use as salvage therapy for patients who fail amphotericin B deoxycholate or who are intolerant to it. In addition, L-AMB was shown to have fewer adverse events and to reduce breakthrough invasive fungal infections when used as empiric therapy for persistent fever in febrile neutropenic patients, although no change in overall outcome was noted. However, despite the improved therapeutic index of these amphotericin B formulations as compared with amphotericin B deoxycholate, they have not been shown superior in efficacy. The use of these preparations in patients with severe fungal infection who have baseline renal insufficiency or who are at very high risk for nephrotoxicity (e.g., allogenic bone marrow transplant recipients receiving nephrotoxic medications) is recommended. In addition, in patients who have infections that respond poorly

Table 207.2 Amphotericin B lipid formulations

Amphotericin B lipid formulations	Structure	Indications	Dosages
Amphotericin B lipid complex (ABLC) (Abelcet)	Ribbonlike structures of a bilayered membrane formed by combining a 7:3 mixture of dimyristoyl phosphatidylcholine and dimyristoyl phosphatidylglycerol with amphotericin B (drug/lipid ratio of 1:1)	Invasive fungal infections in patients refractory or intolerant to amphotericin B deoxycholate	5 mg/kg/d as single infusion
Amphotericin B cholesteryl sulfate complex colloidal dispersion (ABCD), (Amphotec)	Disklike structures of cholesterol sulfate complexed with amphotericin B in equimolar concentration	Treatment of patients who either failed or are intolerant to amphotericin B deoxycholate; increased toxicity noted	3–4 mg/kg/d (up to 6 mg/kg/d)
Liposomal amphotericin B (Ambisome)	Small unilamellar liposomes about 55–75 nm in diameter made up of a bilayer membrane of hydrogenated soy phosphatidylcholine and distearoyl phosphatidylglycerol stabilized by cholesterol and combined with amphotericin B in a 2:0.8:1:0.4 ratio	Treatment of patients with *Aspergillus* species, *Candida* species, and/or *Cryptococcus* species infection refractory to amphotericin B deoxycholate, or in patients in whom renal impairment or toxicity precludes the use of amphotericin B deoxycholate; empirical treatment for presumed fungal infection	3–5 mg/kg/d as single infusion

Data from Hiemenz JW, Walsh TJ. Lipid formulations of amphotericin B: recent progress and future directions. *Clin Infect Dis.* 1996;22(Suppl 2):5133.

to amphotericin B, including infections caused by members of the order *Mucorales*, *Fusarium* species, and other invasive molds such as *Aspergillus*, it is possible that high doses of lipid formulations of amphotericin B will improve outcome. Although increases in the doses of lipid formulations are also associated with increased toxicity, their increased therapeutic index has largely resulted in replacement of amphotericin B deoxycholate for invasive fungal infections.

AZOLES

Similar to the polyenes, azole antifungal agents also target ergosterol albeit through an alternative mechanism of action. By binding to lanosterol 14-α-demethylase, these agents inhibit ergosterol biosysnthesis, resulting in disruption of the fungal cell membrane. The primary members of this class used in the treatment of invasive mycosis are fluconazole, itraconazole, voriconazole, and posaconazole.

Fluconazole is commercially available in both an oral and an intravenous preparation. Following oral administration, fluconazole is nearly completely absorbed with a bioavailability >90% and is widely distributed into the tissues, including the CSF (concentrations in CSF and urine concentrations are 70% to 90% of those found in the plasma). The half-life of fluconazole is approximately 30 hours, and its primary route of elimination is as unchanged drug in the urine. Doses may need to be adjusted in renal failure.

Itraconazole is available in oral capsule and solution formulations. Unlike fluconazole, itraconazole capsules have low and erratic bioavailability due to poor water solubility, which may be influenced by gastric pH. An oral solution and intravenous itraconazole formulation are available, both of which utilize hydroxy-propyl-β-cyclodextrin as an excipient to overcome the insolubility of itraconazole in aqueous solution. The oral solution has improved the bioavailability and consistency of plasma levels of itraconazole. Due to its high lipophilicity itraconazole is extensively distributed to the tissues. Itraconazole is highly protein bound (>99%) and is extensively metabolized by cytochrome P450 3A4, with less than 1% of drug found unchanged in the urine. The half-life of itraconazole is 24 hours. Due to the extensive hepatic metabolism, the oral formulations do not require dose adjustments in renal failure.

Voriconazole is available as an oral and intravenous preparation. Following oral administration, the bioavailability of voriconazole is approximately 90%. Voriconazole undergoes extensive hepatic metabolism primarily by cytochrome P450 2C19 and, to a lesser extent, 2C9 and 3A4 isoenzymes. The bioavailability of voriconazole may be influenced by polymorphisms in 2C19, with homozygous poor metabolizers having peak plasma concentrations and overall

exposures, as measured by the plasma area under the curve, 4-fold higher than those of homozygous extensive metabolizers. Compared to the other azoles, the half-life of voriconazole is variable, ranging between 6 hours and 24 hours. Significant intra- and interpatient variability has also been reported with voriconazole and may be the result of drug interactions as well as differences in metabolism between patients due to polymorphisms in the cytochrome P450 enzyme 2C19. At higher doses voriconazole demonstrates nonlinear kinetics in adults due to saturable metabolism and is distributed extensively to the tissues. The intravenous formulation contains a cyclodextrin excipient (sulfobutyl ether β-cyclodextrin), which may accumulate with decreased renal function.

Although posaconazole was previously available only PO, now an oral tablet and an intravenous formulation are available. The bioavailability of the oral suspension is greatly enhanced when coadministered with a high-fat meal. In addition, agents that increase the gastric pH (e.g., proton pump inhibitors and H_2 blockers) or motility (e.g., metoclopramide) also significantly reduce the bioavailability of the oral suspension. Posaconazole has a large volume of distribution, suggesting extensive tissue distribution, and is extensively protein bound (99%). Unlike itraconazole and voriconazole, posaconazole does not undergo phase I metabolism (mediated by cytochrome P450 enzymes) but instead is metabolized via glucuronidation (phase II metabolism). The half-life of posaconazole is 25 hours, and the majority of elimination occurs in the feces as unchanged drug.

The azole antifungals are generally well tolerated, with a mild side-effect profile consisting of nausea, vomiting, headache, dizziness, rash, pruritus, and anorexia, but these agents can also have more serious dose-limiting toxicities such as hepatic toxicity, serious dematologic effects, visual toxicities, central nervous system (CNS) side effects, and cardiovascular effects. The milder dose-related toxicities are uncommon, occurring in fewer than 5% of patients, but vary according to specific agents. Fluconazole is generally the best-tolerated agent of the class although alopecia with long-term high doses can occur. Notably, itraconazole oral solution may be associated with significant gastrointestinal adverse effects, including nausea, vomiting, and osmotic diarrhea, due to the cyclodextrin component. In addition, administration of itraconazole at doses greater than 400 mg/day can cause hypokalemia, hypertension, and pedal edema. Voriconazole has been associated with several adverse effects, including visual disturbances, CNS toxicity, hepatotoxicity, and cutaneous phototoxicity. Some of these adverse effects have been shown to be concentration dependent, particularly the CNS toxicities and/or visual disturbances. Visual disturbances, which may manifest as photophobia or abnormal vision, are transient, have not resulted in long-term toxicity, and abate with continued treatment. Posaconazole has been associated with few systemic toxicities, most commonly gastrointestinal intolerance, although this may reflect the poor bioavailability and low systemic exposures with the oral solution.

Each member of this class can cause hepatotoxicity although fluconazole is rarely associated with dose-limiting liver abnormalities. Typically, the liver dysfunction is characterized by asymptomatic elevation of transaminases in the range of two to three times the upper limit of normal. Mild, asymptomatic transaminase elevations can be managed without drug discontinuation and close follow-up. Symptomatic liver dysfunction, however, requires discontinuation of treatment. Enzyme elevations are reversible but may take months to normalize. However, cases of fatal hepatotoxicity have been reported with itraconazole, voriconazole, and posaconazole, although the latter appears to be associated with less hepatotoxicity due to its lack of hepatic metabolism.

Due to similarities between ergosterol and cholesterol biosynthesis, drug interaction can occur via inhibition of cytochrome P450 enzymes by azole antifungals. In addition, itraconazole, voriconazole, and, to a lesser extent, fluconazole are also substrates of cytochrome P450 enzymes. Although posaconazole does not undergo phase I metabolism, it is an inhibitor of cytochrome P450 3A4. In addition, posaconazole is a substrate for P-glycoprotein efflux. Thus, coadministration of azoles with drugs that are substrates, inhibitors, or inducers of these enzymes may result in significant drug interactions (Table 207.3). Therefore, careful consideration is required prior to the addition or removal of an azole to or from an existing drug regimen. Monitoring patients for signs and symptoms of toxicity or subtherapeutic effects, and when possible measuring concentrations of coadministered drugs, may also be necessary. The clinician is advised to seek out detailed drug interactions, which are available in several updated extensive on-line databases including www.drugs.com, Micromedex®

Table 207.3 Antifungal drug–drug interaction

Drug	CYP 2C19	CYP 2C9	CYP 3A4	Other selected interactions
Fluconazole	Minimal inhibitor	Moderate inhibitor	Moderate inhibitor	• Reduced concentrations with inducers of CYP enzymes
Itraconazole		Minimal inhibitor	Strong inhibitor; substrate	• Reduced concentrations with inducers of CYP enzymes • Reduced absorption with proton pump inhibitors, H_2 blockers, metoclopramide
Posaconazole			Strong inhibitor	• Reduced concentrations with rifampin/rifabutin, phenytoin, efavirenz coadministration • Reduced absorption with proton pump inhibitors, H_2 blockers, metoclopramide
Voriconazole	Strong inhibitor; substrate	Moderate inhibitor; substrate	Moderate inhibitor; substrate	• Reduced concentrations with inducers of CYP enzymes
Caspofungin				• Reduced concentrations with rifampin, phenytoin, efavirenz, dexamethasone, nevirapine, or carbamazepine coadministration • May reduce tacrolimus concentrations
Micafungin				• Increased sirolimus or nifedipine concentrations when coadministered
Flucytosine				• Nephrotoxicity from amphotericin B may lead to toxic levels of flucytosine

Note: The clinician is advised to seek out detailed drug interactions which are available in several updated extensive on-line databases including www.drugs.com, Micromedex® (www.micromedexsolutions.com), Lexicomp® (www.uptodate.com), the Aspergillus website (www.aspergillus.org.uk), and others.

Fluconazole has been used extensively in the treatment of systemic yeast infections, including primary therapy for candidemia, particularly that caused by *Candida albicans* but also other yeasts, including *Candida tropicalis, Candida parapsilosis*, and *Candida glabrata*. Only *Candida krusei* is inherently resistant to fluconazole, although resistance may develop to fluconazole and other azoles in *C. glabrata*. Fluconazole is also effective in the therapy of cryptococcal infections, including meningitis, with most use for consolidation therapy after initial therapy with amphotericin B and for long-term suppressive therapy in immunosuppressed patients, including those with acquired immunodeficiency syndrome (AIDS). Fluconazole is an alternative, when appropriate, to amphotericin B in the management of *Coccidioides immitis* meningitis. In addition, fluconazole is indicated for the prophylaxis of yeast infection in patients with chemotherapy-induced neutropenia.

Itraconazole is indicated for the therapy of endemic mycoses, including histoplasmosis, blastomycosis, and sporotrichosis, usually used after amphotericin B in severely ill patients or as primary therapy in patients with less extensive infection. It may be used for sequential therapy following initial amphotericin B in invasive aspergillosis, as primary therapy in less immunosuppressed patients with less extensive infection, and as prophylaxis in patients with chemotherapy-induced neutropenia and in allogeneic stem cell transplant recipients with graft-versus-host disease receiving corticosteroids. In addition, itraconazole is effective in cutaneous and systemic infection resulting from dematiaceous fungi, including *Exserohilum* species, *Exophiala* species, and *Bipolaris/Curvularia* species.

Voriconazole has a broad spectrum of activity against *Aspergillus* species, including *Aspergillus terreus*, *Candida* species, including those resistant to fluconazole (*C. krusei*), *Pseudallescheria boydii/Scedosporium apiospermum*, and *Fusarium* species. In vitro activity has also been demonstrated against *Cryptococcus neoformans*, *Blastomyces dermatitidis, C. immitis*, and *Histoplasma capsulatum*. Voriconazole has become the drug of choice for the primary treatment of invasive aspergillosis and infections caused by *P. boydii/S. apiospermum* and *Fusarium* species. It is also indicated for invasive candidiasis and esophageal candidiasis, including fluconazole-resistant species, although cross-resistance (particularly in *C. glabrata*) can occur as it can with posaconazole and the other azoles. Voriconazole has also been shown to be effective as early or pre-emptive therapy for presumed *Aspergillus* infections.

Posaconazole has been shown to be effective for the salvage treatment of invasive aspergillosis and invasive candidiasis, although it is only licensed in Europe for the former and has a limited role in serious *Candida* infections due to the lack of an intravenous formulation. Similar to voriconazole, posaconazole has a broad spectrum of activity against a wide range of both yeast and filamentous fungi, including *Aspergillus* and *Candida* species, the dimorphic fungi *C. immitis/posadasii*, *H. capsulatum*, and *B. dermatitidis*, and *Cryptococcus* species. However, unlike voriconazole, posaconazole also has in vitro and in vivo activity against members of the order *Mucorales*. Studies have also demonstrated the potential utility of this agent in the treatment of invasive infections caused by *Fusarium* species. Excellent efficacy of posaconazole has also been demonstrated as antifungal prophylaxis both in neutropenic patients and in allogeneic stem cell transplant recipients post-engraftment with graft-versus-host disease.

Monitoring of antifungal concentrations within biologic fluids has gained attention, and this practice is routinely used by some institutions. The majority of antifungal therapeutic drug monitoring is with the azoles voriconazole, posaconazole, and itraconazole. Several groups have reported associations between voriconazole concentrations and both clinical efficacy and toxicity. For voriconazole, trough concentrations within the bloodstream of <1 μg/mL have been associated with clinical failure in patients with invasive fungal infections, while toxicities have been reported with elevated levels (>5.5 μg/mL in one study). Although an exact range of safe and effective voriconazole concentrations has not been definitively set, a therapeutic range with a high probability of success and low probability of toxicity may be between 1.5 and 4.5 μg/mL. For posaconazole, the exact threshold associated with clinical efficacy for the treatment of invasive fungal infections remains unknown. However, as prophylaxis, studies have suggested that concentrations of 0.5 to 0.7 μg/mL may be used as a target level. Therapeutic drug monitoring may also be performed with itraconazole. However, the interpretation of these results is dependent upon the assay used for measurement of drug concentrations. When measured by analytical assays, such as high performance liquid chromatography (HPLC) or liquid chromatography mass spectrometry (LC/MS), levels of 0.5 μg/mL have been reported to be associated with improved prophylactic efficacy. Some laboratories still use a bioassay to measure itraconazole concentrations. This method is unable to distinguish between itraconazole and the active metabolite hydroxy-itraconazole, resulting in concentrations that are higher than that reported by analytical means. Unfortunately, levels measured by bioassay may be between 2 and 10 times higher than those measured by HPLC or LC/MS.

ECHINOCANDINS

The echinocandins anidulafungin, caspofungin, and micafungin are large, cyclic, semisynthetic lipopeptides. Through noncompetitive inhibition of glucan synthase, these agents deplete β-1,3-glucan, a primary component of the cell wall of many pathogenic fungi, including *Aspergillus* and *Candida* species.

Due to their high molecular weight and poor bioavailability, each member of this class is available only for intravenous administration. Each echinocandin contains a hexapeptide nucleus. However, differences in the *N*-acyl side chain are responsible for variability in the physiochemical properties among these agents. Anidulafungin is not metabolized but rather undergoes spontaneous chemical degradation to an open-ring peptide following intravenous administration. This echinocandin is also extensively protein bound (range 97% to 99%). The majority of the plasma concentration–time profile is characterized by a half-life of approximately 26 hours, followed by a long terminal half-life (52 hours). Caspofungin does undergo phase I metabolism (hydrolysis and *N*-acetylation) as well as some spontaneous chemical degradation to an open-ring peptide. However, distribution to the tissues, not excretion or metabolism, is the primary determinant of plasma clearance. Similar to anidulafungin, a half-life between 9 and 11 hours characterizes the majority of the plasma concentration–time profile, followed by a long terminal half-life of 40 to 50 hours. Caspofungin is also extensively protein bound (97%). Micafungin does undergo limited phase I metabolism. However, the primary route of elimination is as unchanged drug in the feces. Similar to anidulafungin and caspofungin, micafungin is also extensively protein bound (99.5%), with an elimination half-life between 13 and 15 hours.

Due to their inhibition of glucan synthase, a fungal-specific target without a mammalian homolog, the echinocandins are very well tolerated with few clinically significant drug

interactions. The primary adverse effects reported in clinical trials are generally mild to moderate in severity and include rash, headache, nausea, vomiting, diarrhea, and infusion-related reactions and in clinical use are rarely dose-limiting. Mild elevations in transaminases and alkaline phosphatase have also been reported. None of the members of this class act as inhibitors or inducers of cytochrome P450 isoenzymes, nor do they undergo extensive metabolism by these enzymes. Table 207.3 lists potential drug–drug interactions associated with the echinocandins.

Therapeutic uses

The echinocandins have a broad spectrum of activity against *Candida*, including non-albicans species and isolates resistant to fluconazole, and *Aspergillus* species. However, these agents lack activity against *Cryptococcus* species, *Fusarium* species, and the *Mucorales*. Each member of this class has been shown to be effective in the treatment of candidemia, invasive candidiasis, and esophageal candidiasis. In addition, caspofungin and micafungin have also been shown to be effective in the treatment of invasive aspergillosis, including in patients with refractory infections, although only caspofungin is licensed for that indication. Caspofungin has also been shown to be effective in the setting of febrile neutropenia, whereas micafungin is efficacious as prophylaxis in patients with neutropenia.

FLUCYTOSINE

The clinical usefulness of flucytosine (5-FC) is limited by its narrow spectrum of activity, frequent emergence of resistance, and toxicity. Flucytosine is usually administered at a dosage of 150 mg/kg/day in four divided doses, although 100 mg/kg/day in four divided doses may be used in combination with amphotericin B for cryptococcal meningitis. More than 90% of the drug is excreted unchanged in the urine, and patients with renal insufficiency require dosage reduction. As an approximation, the total daily dose should be reduced to 75 mg/kg with a creatinine clearance of 26 to 50 mL/min and to 37 mg/kg when the creatinine clearance is 13 to 25 mL/min. In azotemic patients, blood levels should be measured and dosage should be adjusted so that serum levels do not exceed 50 to 100 μg/mL. The drug readily diffuses to the CSF and achieves concentrations of about 74% of serum. Flucytosine is usually well tolerated and results in minor and uncommon adverse effects, such as rash, diarrhea, and mild hypertransaminasemia. The presence of azotemia or the concomitant use of amphotericin B might exacerbate the toxicity, resulting in severe leukopenia, thrombocytopenia, and enterocolitis. These complications seem to occur in many, but not all, patients with blood levels exceeding 100 μg/mL.

Flucytosine has been used extensively to treat chromomycosis. It is not used alone because of the rapid development of resistance and the availability of other less toxic agents, although it has activity in candidiasis and cryptococcosis. Importantly, 5-FC has been shown to have synergistic effects in combination with amphotericin B against most isolates of *Candida, C. neoformans*, and possibly *Aspergillus*. The combination of amphotericin B and 5-FC has been proved useful in the treatment of cryptococcal meningitis in terms of more rapid sterilization of CSF and possibly in reducing rate of relapse. Flucytosine has been used with amphotericin B for invasive *Aspergillus* infections as well as in the therapy of refractory candidemia, although its benefit in these infections has not been shown in controlled trials. Flucytosine has also been used in combination with fluconazole in both cryptococcal infections and against *Candida*.

NEW THERAPIES

Investigational azoles

New azoles are in various stages of development, including isavuconazole (BAL4815 and the oral prodrug BAL8557) and ravuconazole. Isavuconazole has been shown to have a broad spectrum of activity against *Candida* species, *C. neoformans*, *Aspergillus* species, and other opportunistic molds and yeasts. Results from a clinical trial comparing isavuconazole to voriconazole for invasive aspergillosis have recently been released suggesting similar efficacy of the agents. A similar broad spectrum of activity has been demonstrated for ravuconazole, including the *Mucorales*, although clinical development is uncertain.

Other agents

The fungal Cyp51 inhibitors VT-1129 and VT-1161 inhibit the biosynthesis of ergosterol. These agents are highly selective for fungal Cyp51 compared to mammalian cytochrome P450 enzymes,

thus there is the potential for fewer drug interactions compared to the azoles. Both agents demonstrate potent activity against yeasts, including *Candida* and *Cryptococcus* species, and VT-1161 is currently in early clinical trials. T-2307 is an aromatic diamidine with some structural similarities to pentamidine. Although the mechanism of action is not fully understood, this agent demonstrates potent activity against *Candida* species, including azole-resistant isolates, *C. neoformans*, and *Aspergillus fumigatus*. E1210 inhibits inositol acylation early in the glycosylphosphatidylinositol biosynthesis pathway in fungi but not in humans. This agent has potent, broad-spectrum activity against fungi, including *Candida*, *Aspergillus*, *Fusarium*, and *Scedosporium* species. However, E1210 is inactive against *Candida krusei* and members of the order *Mucorales*. One novel strategy that is currently being evaluated targets the epigenetic regulation in fungi. MGCD290 is a fungal deacetylase inhibitor that has been shown in vitro to act in synergy with fluconazole, voriconazole, and posaconazole, including isolates that are usually resistant to these azoles. When combined with fluconazole, synergy was observed against *Candida* species, including *C. krusei*, as well as some *Aspergillus* species, and with voriconazole, synergy was observed against most *Mucorales* isolates. Nikkomycin Z (VFS-1), which targets the synthesis of the cell wall component chitin, has shown activity against *C. immitis* and *B. dermatitidis* alone and against *Candida* species, *C. neoformans*, and *A. fumigatus* in combination with azoles.

FUTURE DIRECTIONS

Despite the increasing number of antifungal agents, treatment of fungal diseases still remains unsatisfactory. In many cases, host factors such as neutropenia, immunosuppression associated with transplantation, uncontrolled hematologic malignancy, or other causes of underlying immunosuppression play a pivotal role as important risk factors for the acquisition of fungal infections as well as for response to therapy. Future research efforts should be aimed at reducing risk of acquiring fungal infections as well as improving host defenses against these opportunistic pathogens. In addition, the development of improved diagnostics are needed to allow early and targeted therapy for specific mycoses, including drug-resistant pathogens. Finally, combination therapy may be a means for improving overall outcomes in these difficult-to-treat infections.

208. Antiviral therapy

Thomas N. Kakuda and Frank L. Tomaka

Successful antiviral therapy continues to be one of the most difficult challenges facing the healthcare provider today. Certain intrinsic characteristics of the major human viral pathogens contribute to this challenge. Because all viruses parasitize host cell enzymes and structures to varying degrees, designing or discovering drugs that specifically target the virus without toxicity is difficult. Additionally, many viruses establish a latent infection in the host, during which time they are essentially quiescent. Elimination of such latent viruses from the host has not been possible to date. Some of the most serious viral infections today stem from the reactivation of latent viruses during periods of impaired cell-mediated immunity. Additionally, an ongoing challenge in antiviral therapy is the development of drug resistance due to mutating viruses and/or transmission of resistant viruses.

Most of the currently available antiviral agents target the virus by exploiting differences in viral and host replication processes. Many viruses have their own specific DNA polymerases, which are more susceptible to inhibition by specific drugs than the cellular DNA replication enzymes. Thus many antiviral agents are nucleoside/nucleotide analogs. In addition, some of these compounds accumulate preferentially in virus-infected cells or are activated by virus-encoded enzymes, increasing their specificity. Nevertheless, unlike many antibacterial agents, most antiviral agents remain far from being "magic bullets" and can have considerable dose-related toxicities.

This chapter describes the US Food and Drug Administration (FDA)-approved antiviral drugs, their primary uses, their pharmacokinetics and potential interactions, and the major toxicities associated with their administration (Table 208.1).

Antiretrovirals associated with the treatment of human immunodeficiency virus (HIV) are discussed in Chapter 99, HIV infection: antiretroviral therapy.

Tenofovir
Valacyclovir
Valganciclovir
Vidarabine
Zanamivir

ACYCLOVIR

Acyclovir, a guanine derivative, has in vitro activity against herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus (VZV), Epstein–Barr virus (EBV), and cytomegalovirus (CMV), but it is used primarily in HSV and VZV infections. Acyclovir is preferentially taken up by

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.
© Cambridge University Press 2015.

HSV-infected cells and is phosphorylated by HSV thymidine kinase, which is necessary for conversion to the active triphosphate form. It inhibits viral DNA polymerase and causes DNA chain termination when incorporated into replicating DNA. Valacyclovir (discussed later in this chapter) is a prodrug of acyclovir.

Acyclovir may be used for primary episodes of genital herpes to reduce the time of viral shedding and time to healing at a dose of 200 mg orally five times per day for 10 days. It can also be used for treatment of recurrent episodes with 200 mg orally five times a day for 5 days at the first sign of a recurrence. Acyclovir can be used as chronic suppressive therapy to decrease the incidence of recurrent genital herpes at 400 mg orally twice daily. Therapy should be evaluated periodically to reassess the need for chronic suppression. An ointment is available for primary herpes genitalis, but its impact on the natural course of the infection is marginal. Many physicians use acyclovir for the treatment of herpes labialis in a fashion similar to the treatment of genital herpes.

Acyclovir reduces mortality in HSV encephalitis and should be used at high dosages (10–15 mg/kg intravenously [IV] every 8 hours) for 14 to 21 days. Severe mucosal and cutaneous infections in immunocompromised patients may require IV therapy (5 mg/kg every 8 hours) for 7 days. HIV-1-infected patients often require oral suppression to prevent recurrences. Refractoriness to therapy in such patients may indicate the development of acyclovir resistance.

Acyclovir is also active against VZV, but treatment of VZV infections requires higher dosages than treatment of uncomplicated HSV infections. Acyclovir, 800 mg five times daily for 7 to 10 days, should be used in patients with herpes zoster (shingles) to prevent dissemination and in an attempt to shorten the time to healing. In immunocompromised patients, the recommended dose is 10 mg/kg IV every 8 hours for 7 days. Such treatment does not convincingly alter the subsequent development of postherpetic neuralgia, however. Ophthalmic zoster, involving the first branch of the trigeminal nerve, warrants evaluation by an ophthalmologist and immediate therapy, which may be given orally. VZV has also been associated with the syndrome of acute retinal necrosis, which should be treated as a medical emergency.

Acyclovir 800 mg orally every 6 hours for 5 days is effective in the treatment of primary varicella or chickenpox, shortening the duration and severity of illness when begun within 24 hours after the onset of rash. The recommended dose for the treatment of immunocompromised patients is 10 mg IV every 8 hours for 7 to 10 days. Chickenpox in pregnant women may be life threatening, particularly when varicella pneumonia develops. Acyclovir treatment of neonates with VZV or HSV infection is also indicated.

Oral acyclovir, 400 mg five times a day, or IV therapy is effective in preventing mucocutaneous HSV infections in both solid organ and bone marrow transplant patients. It may be given longer term (6 months) to decrease the incidence of VZV infections in bone marrow transplant recipients.

Acyclovir may be of some benefit in EBV-induced lymphoproliferative disease in immunocompromised patients, but it is not clinically useful in EBV disease such as mononucleosis. Incidentally, acyclovir is of no utility in the treatment of chronic fatigue immune dysfunction syndrome (CFIDS)/chronic fatigue syndrome (CFS), because this syndrome has no causal association with EBV infection. Acyclovir is active and has been clinically useful against *Herpesvirus simiae*, or B virus, an endemic herpesvirus of certain primate species, which, when transmitted to humans has resulted in severe neurologic disease and death.

Pharmacokinetics

Acyclovir has poor water solubility and hence poor oral bioavailability (10%–15%) but good tissue distribution; the low oral bioavailability necessitates frequent administration which is partly resolved by using either the IV formulation or valacyclovir. The serum half-life is 2.5 to 3 hours. Acyclovir is excreted renally and dose adjustment is necessary in patients with impaired renal function.

Major toxicities

Central nervous system (CNS) effects range from confusion to seizures and coma, especially in the settings of renal insufficiency, underlying altered mental status, and old age. Renal failure may occur from precipitation in the renal tubules. When administering high IV doses, it is important to ensure adequate hydration of the patient. Acyclovir is potentially teratogenic, but inadvertent or therapeutic administration during pregnancy has occurred without obvious adverse effects.

Drug interactions

Acyclovir may potentiate or be potentiated by drugs that decrease renal function or compete for active tubular secretion. Coadministration of acyclovir with cimetidine, mycophenolate mofetil, or probenecid may increase acyclovir exposure although dose adjustment is usually not necessary because of the wide therapeutic index of acyclovir. Acyclovir may increase cyclosporine and theophylline exposure.

ADEFOVIR

Adefovir dipivoxil is a nucleotide analog that inhibits reverse transcriptase. It is indicated for the treatment of chronic hepatitis B infection with active viral replication and either elevated serum aminotransferases (alanine aminotransferase [ALT] or aspartate aminotransferase [AST]) or histologically active disease. Adefovir competitively inhibits hepatitis B virus (HBV) DNA polymerase, causing DNA chain termination. The recommended dose of adefovir is 10 mg daily. HIV resistance may emerge in chronic hepatitis B patients treated with adefovir but with unrecognized or untreated HIV infection.

Pharmacokinetics

Following oral intake, adefovir dipivoxil is readily converted to adefovir. It is renally excreted by both glomerular filtration and tubular secretion. The dosing interval should be adjusted in patients with renal impairment.

Major toxicities

Associated adverse events include asthenia, headache, abdominal pain, gastrointestinal (GI) upset, pruritus, lactic acidosis, hepatitis, hepatomegaly with steatosis, and nephrotoxicity with prolonged use. An exacerbation of hepatitis can occur when treatment is discontinued.

Drug interactions

Adefovir may potentiate or be potentiated by drugs that decrease renal function or compete for active tubular secretion.

AMANTADINE

Amantadine hydrochloride (1-adamantanamine hydrochloride) is used to treat Parkinson's disease and as an antiviral agent that prevents uncoating of influenza A virus after host cell entry. In 2008/2009, it was determined that widespread resistance exists to amantadine, among circulating influenza A strains. It is therefore no longer recommended for prevention or treatment.

BOCEPREVIR

Boceprevir and telaprevir (discussed later) represent the first orally administered direct-acting antivirals (DAA) against hepatitis C virus (HCV). Both are HCV NS3/4A serine protease inhibitors; boceprevir is indicated for patients with compensated liver disease, including cirrhosis, who are previously untreated or who have failed previous interferon and ribavirin therapy, including prior null responders, partial responders, and relapsers. When initiating therapy with boceprevir, patients should receive a 4-week lead-in period with pegylated interferon (peginterferon alfa) and ribavirin followed by the addition of boceprevir 800 mg three times daily with food. Treatment is for 24 and 32 weeks in those who are treatment naïve and treatment experienced, respectively. The need for continued peginterferon/ribavirin treatment is then determined by virologic response (response-guided therapy) at week 4 (i.e., after the lead-in period), 8, and 24 as well as prior treatment history, and presence or absence of cirrhosis upon liver biopsy.

Pharmacokinetics

Boceprevir is formulated as a 1:1 mixture of two diastereomers. In plasma, a 2:1 ratio is observed favoring the active diastereomer. It is rapidly absorbed and food increases its exposure. Metabolism of boceprevir is via aldo-keto reductase (AKR) to inactive ketones. The average terminal elimination half-life of boceprevir is 3.4 hours.

Major toxicities

Associated adverse events for the combination of boceprevir, peginterferon, and ribavirin include fatigue, anemia, nausea, headache, and dysgeusia. Patients should be closely monitored for anemia, hypersensitivity, and neutropenia.

Drug interactions

Boceprevir is a substrate and potent CYP3A inhibitor. Coadministration of boceprevir with alfuzosin, cisapride, drospirenone, pimozide, rifampin, St. John's wort (*Hypericum perforatum*),

ergot derivatives (i.e., dihydroergotamine, ergonovine, ergotamine, or methylergonovine), certain anticonvulsants (i.e., carbamazepine, phenobarbital, or phenytoin), certain HMG-CoA reductase inhibitors (i.e., lovastatin or simvastatin), certain phosphodiesterase type 5 inhibitors when used in the treatment of pulmonary hypertension (i.e., sildenafil and tadalafil), or certain sedative/hypnotics (i.e., oral midazolam or triazolam) is contraindicated. It is not recommended to coadminister boceprevir and the following medications: dexamethasone, rifabutin, salmeterol, inhaled corticosteroids, and certain HIV protease inhibitors (i.e., atazanavir/ritonavir, darunavir/ritonavir, or lopinavir/ritonavir). The dose of colchicine or phosphodiesterase type 5 inhibitor when used for erectile dysfunction (e.g., sildenafil, tadalafil, or vardenafil) should be adjusted when coadministered with boceprevir.

CIDOFOVIR

Cidofovir is an acyclic nucleoside derivative with antiviral activity. Cidofovir was designed to minimize the resistance that develops in response to nucleoside analogs that require phosphorylation by viral enzymes, such as acyclovir and ganciclovir. Although cidofovir must be diphosphorylated to become active, it does not require phosphorylation by viral kinases. Rather, cidofovir is activated by cellular enzymes. Cidofovir is more active against herpesvirus DNA polymerases than cellular DNA polymerases and thus has selective antiviral activity.

Cidofovir is primarily used for the treatment of CMV retinitis in acquired immunodeficiency syndrome (AIDS) patients. Its use in other CMV infections and in other immunocompromised patients has not been adequately evaluated. Cidofovir has been effective in delaying the progression of CMV retinitis in AIDS patients, including those who have failed ganciclovir or foscarnet therapy. Ganciclovir-resistant strains of CMV, which carry mutations in the UL97 phosphokinase gene, generally remain susceptible to cidofovir. However, other ganciclovir-resistant mutants, especially those carrying mutations in the DNA polymerase gene may be cross-resistant to cidofovir. CMV strains resistant to ganciclovir, foscarnet, and cidofovir have also been described.

Intravenous cidofovir is administered with probenecid to prevent rapid secretion of the drug by the renal tubules. Creatinine clearance should be estimated by calculation or directly measured before initiating therapy with cidofovir. The nephrotoxic potential of cidofovir is such that a creatinine clearance less than 55 mL/min, a serum creatinine greater than 1.5 mg/dL, or 2+ proteinuria is a contraindication to its use. Induction therapy with cidofovir is initiated at a dosage of 5 mg/kg once weekly for 2 weeks, followed by the same dose once every 2 weeks as maintenance therapy. Intravenous saline prehydration with 1 L of normal saline immediately before cidofovir infusion is mandatory to prevent nephrotoxicity. If possible, an additional liter of saline should be administered with and after cidofovir over a 1- to 3-hour period. In addition, great care should be taken to monitor renal function with both urine and serum measurements, and the importance of taking the probenecid should be emphasized. Probenecid is administered as follows: 2 g 3 hours before infusion and 1 g at 2 and 8 hours after infusion.

Pharmacokinetics

Approximately 70% of cidofovir is eliminated unchanged by the kidneys. Its plasma half-life is approximately 2.5 hours, but it has a long-lasting antiviral effect. The latter is the result of the intracellular persistence of its active phosphorylated metabolite.

Major toxicities

As described, the major toxicity of cidofovir is its nephrotoxicity. Neutropenia has occurred in approximately 20% of cidofovir recipients in clinical trials.

Drug interactions

The most important drug interactions are those leading to additional nephrotoxicity. Additive or synergistic nephrotoxic effects with other drugs known to result in nephrotoxicity, such as aminoglycosides or amphotericin B, have not been studied. In addition, the potential for probenecid effects on the metabolism and disposition of other drugs must be considered.

DOCOSANOL

Docosanol is a saturated fatty alcohol that can reduce the duration of cold sores associated with HSV. Its mechanism of action is not entirely known but may involve inhibition of fusion between the viral envelope and human host cell.

Docosanol 10% is available over the counter and is applied topically to the cold sore five times a day for up to 10 days. The most commonly reported side effects include headache and local skin irritation.

ENTECAVIR

Entecavir is a nucleoside analog that works by inhibiting HBV polymerase. It is indicated for the treatment of chronic hepatitis B infection in adults with evidence of active viral replication and either persistently elevated serum aminotransferases (ALT or AST) or histologically active disease. For the treatment of chronic hepatitis B infection in adults and adolescents (16 years old or older) who are nucleoside treatment naïve, the dosing is 0.5 mg daily. For patients with hepatitis B viremia also being treated with lamivudine or who have lamivudine and/or telbivudine resistance, the dose is 1 mg daily. Dose adjustment is necessary for patients with decreased renal function. Like adefovir, HIV resistance may emerge in chronic hepatitis B patients treated with entecavir but with unrecognized or untreated HIV infection.

Pharmacokinetics

Entecavir has a bioavailability of 100% following oral administration when the patient is fasting. It is predominantly eliminated by the kidney as unchanged drug. It undergoes both glomerular filtration and tubular secretion.

Major toxicities

Commonly reported side effects include headaches, fatigue, dizziness, and GI upset. Severe acute exacerbations of hepatitis have occurred when treatment has been discontinued.

Drug interactions/precautions

Entecavir may potentiate or be potentiated by drugs that decrease renal function or compete for active tubular secretion.

FAMCICLOVIR

Famciclovir, a diacetyl 6-deoxy analog of penciclovir (9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine), is a nucleoside analog that has a spectrum of activity similar to that of acyclovir. Famciclovir is an inactive prodrug of penciclovir. After oral administration, famciclovir is rapidly metabolized to active penciclovir, which is phosphorylated by viral thymidine kinase and has a mechanism of action similar to acyclovir. Famciclovir is more bioavailable than acyclovir and has a prolonged intracellular half-life, which permits thrice-daily dosing. Famciclovir is approved for treatment of herpes zoster (500 mg three times daily for 7 days) and is similar to acyclovir in ameliorating the course of the acute attack. It is also claimed, on the basis of two studies, that famciclovir shortens the duration of postherpetic neuralgia. It is also indicated for the treatment and suppression of recurrent genital HSV (treatment: 1000 mg every 12 hours for 1 day; suppression: 250 mg every 12 hours for up to 1 year) and recurrent herpes labialis in immunocompetent patients (1500 mg as a single dose). For the treatment of orolabial or genital herpes in HIV-infected patients, it is recommended that famciclovir 500 mg be given every 12 hours for 7 days.

Pharmacokinetics

Famciclovir is excreted renally. The serum half-life is 2.5 to 3 hours, but the intracellular half-life is 10 to 20 times longer. Dose adjustment is necessary in patients with reduced renal function.

Major toxicities

In clinical trials, no major adverse effects have been reported to date. No adverse effects were observed on embryo–fetal development in animal testing. However, no adequate and well-controlled studies have been conducted in pregnant women. Testicular toxicity was observed in animal models, and decreased fertility was observed in male rats after 10 weeks of administration at 1.9 times the human dosage.

Drug interactions

Probenecid may lead to increased famciclovir levels. Famciclovir may lead to increased digoxin levels.

FOSCARNET

Foscarnet (phosphonoformic acid) binds to pyrophosphate binding sites on viral DNA polymerases and reverse transcriptases. This compound does not bind to cellular DNA polymerases at virus-inhibitory concentrations. Foscarnet is active against all herpesviruses and has some

direct activity in vitro against HIV-1. Foscarnet is used in AIDS patients with CMV retinitis who cannot tolerate or worsen on ganciclovir. Foscarnet is not curative but delays progression to greater than 3 months versus less than 1 month without therapy. Induction treatment is given at 60 mg/kg IV every 8 hours for 2 to 3 weeks, followed by maintenance therapy at 90 mg/kg once daily. Foscarnet is also used in resistant VZV and HSV infections in AIDS patients.

Pharmacokinetics

Foscarnet is excreted renally. Its half-life is variable and highly dependent on renal function, which is invariably impaired by foscarnet. Thus, close monitoring of renal function with dosage adjustment is mandatory in all patients.

Major toxicities

The major toxicity of foscarnet is impairment of renal function. In addition, hypocalcemia, hypophosphatemia, hyperphosphatemia, hypomagnesemia, and hypokalemia may occur.

Drug interactions

Foscarnet may interact with pentamidine, increasing the risk of fatal hypocalcemia, and may have additive effects on anemia due to zidovudine.

GANCICLOVIR

Ganciclovir (9-[1,3-dihydroxy-2-propoxymethyl] guanine, a guanine derivative) is a major antiviral agent used against CMV. It is the active form of the prodrug valganciclovir (discussed later). Ganciclovir is phosphorylated by viral and then cellular kinases and preferentially accumulates in CMV-infected cells. It competitively inhibits viral DNA polymerase and is incorporated into DNA, acting as a chain terminator. Ganciclovir is used primarily in AIDS-associated CMV retinitis, colitis, pneumonitis, and disseminated disease. Efficacy in AIDS is clearly established only for retinitis, in which it slows progression and is not curative. Retinitis is treated with an induction phase (5 mg/kg every 12 hours for 14 to 21 days) followed by maintenance at the same dose once a day. Rarely maintenance may also be given orally as 1000 mg three times daily with food. Patients who fail while receiving maintenance therapy may be "reinduced" or changed to foscarnet. Ganciclovir tablets can also be used for the prevention of CMV disease in patients with advanced HIV infection. The recommended dose for this indication is 1000 mg three times a day with food.

An intravitreal ganciclovir implant for the treatment of CMV retinitis is available. Because such local therapy does not prevent the development of CMV disease elsewhere, most importantly in the contralateral eye, combination therapy with systemic ganciclovir has been studied. A large-scale study demonstrated that oral ganciclovir, albeit at a dosage of 4.5 g/day, prevented the development of retinitis in the unaffected eye almost as well as did IV ganciclovir. CMV retinitis is much less common since the advent of highly active antiretroviral therapy (HAART), and prophylaxis may be unnecessary in those patients achieving immune reconstitution. However, CMV retinitis often occurs in patients in whom antiretroviral therapy has already failed.

Ganciclovir prevents CMV disease in high-risk transplant patients when given for 7 to 14 days at the same dosages as for induction therapy. The duration of maintenance therapy depends on the intensity of immunosuppression and should be given for at least 100 days after the transplant in the case of bone marrow transplant patients. Treatment of established CMV pneumonia in bone marrow transplant patients is effective when combined with IV immunoglobulin.

Pharmacokinetics, major toxicities, and drug interactions

Ganciclovir is excreted renally. Dose reductions based on creatinine clearance are necessary in patients with impaired renal function. The major toxicity of ganciclovir is hematologic, often causing anemia, neutropenia, and thrombocytopenia. All cytotoxic drugs that inhibit cell replication have the potential to significantly increase the marrow toxicity of ganciclovir. These include chemotherapeutic agents, trimethoprim–sulfamethoxazole, dapsone, zidovudine, and other nucleoside analogs. Other adverse events associated with ganciclovir use include renal insufficiency, fever, diarrhea, anorexia, vomiting, and sweating. Cyclosporin, amphotericin B, and other nephrotoxic agents should be used with caution because of the increased risk of combined nephrotoxicity. Probenecid may lead to increased ganciclovir levels.

Ganciclovir has demonstrated teratogenic and carcinogenic effects in animal studies.

IMIQUIMOD

Imiquimod is a topical agent that may be used for the treatment of condyloma acuminata. It can also be used to treat actinic keratosis and superficial basal cell carcinoma. Its mode of action is unknown but it appears to act as an immune response modifier. Imiquimod induces mRNA encoding cytokines, including interferon-α, at the application site. Human papillomavirus (HPV) L1 mRNA and HPV DNA levels decrease significantly following treatment. It has no direct antiviral activity. Systemic absorption appears to be minimal, and local reactions appear to be the major toxicity. However, its long-term effects and safety have not been evaluated.

INTERFERONS

Interferons are naturally occurring glycoproteins with antiviral, antitumor (antiproliferative), and immunomodulatory activities. They are induced by viral infection, especially double-stranded RNA viruses. Interferon-α is primarily synthesized by B lymphocytes and interferon-β by fibroblasts and other cells. Interferon-α and interferon-β are closely related. Interferon-α is actually a heterogeneous family of proteins encoded by multiple similar genes. Interferon-γ is produced by T lymphocytes and is induced by mitogenic stimuli, such as antigen-presenting cells and antigen. Interferon-γ also has macrophage-activating functions and other interleukin activities, modulating the function of other lymphocytes. *Interferon alfacon-1* is not found in nature, but its structure was derived by combining the sequences of various naturally occurring interferons and produced by recombinant DNA technology.

The mechanism(s) of action of interferons is varied. Their antiviral effect is partly mediated by inducing cellular enzymes that lead to a shutdown of protein synthesis in virus-infected cells, as well as activating RNA degradation.

Route of administration and major toxicities

Administration is subcutaneous, intramuscular (IM), or intralesional. Major toxicities commonly observed are flu-like symptoms, fever (in almost all patients treated), myalgias, fatigue, and alopecia. Exacerbation of some autoimmune diseases and psoriasis with interferon has been observed. Depression has been associated with administration of some interferons. Ophthalmologic side effects such as retinal hemorrhages have been rarely reported concomitantly with interferon therapy.

Interferon-α2a

Interferon-α2a (recombinant human protein made in *Escherichia coli*) may be used in the treatment of the following conditions: (1) AIDS-associated Kaposi's sarcoma (the response correlates with extent of HIV-1 progression more than the severity of Kaposi's sarcoma) and (2) chronic hepatitis C (see the following section).

Interferon-α2b

Interferon-α2b (recombinant human protein made in *E. coli*) is used in the treatment of the following conditions:

- Condyloma acuminata: Interferon-α2a is injected intralesionally for the treatment of condyloma acuminata. Injection of 1 million units per lesion is performed with a tuberculin syringe on alternate days, three times a week for 3 weeks. The product literature should be consulted for other details regarding administration and dosage.
- AIDS-associated Kaposi's sarcoma: The dosage is 30 million units/m^2 three times a week, administered IM or subcutaneously. If tolerated, treatment may be continued until resolution of tumors.
- Chronic hepatitis C: Interferon treatment decreases transaminase levels and may lead to sustained virologic response. The benefit extends beyond the period of therapy. Relapse may be treated with combination ribavirin and interferon therapy. Interferon-naïve patients may also be treated with combination therapy. The dosage is 3 million units subcutaneously three times weekly. The optimal duration of therapy in different situations remains to be defined.
- Chronic hepatitis B: A virologic response with loss of eAg (and sAg in some patients) and improved transaminases may occur. Lasting remission may also be occasionally obtained. Interferon-α2b has been administered as 5 million units daily or 10 million units three times a week for this indication.

Interferon-α3n

Interferon-α3n is a purified natural human leukocyte interferon. It is produced by infecting human leukocytes with Sendai virus and then purifying the induced interferon. It is used intralesionally for condyloma acuminata.

Interferon alfacon-1

Interferon alfacon-1 is used in the treatment of chronic hepatitis C. A dose of 9 μg is administered subcutaneously three times a week for 24 weeks.

Peginterferon-α2a

Peginterferon-α2a is a covalent conjugate of interferon-α2a and a PEG (polyethylene glycol) moiety. Pegylation lowers the systemic clearance of interferon-α2a 100-fold, thereby increasing the mean terminal half-life after subcutaneous dosing from 5.1 hours to 80 hours. Peginterferon-α2a is indicated as monotherapy and in combination with ribavirin for the treatment of chronic hepatitis C infection in patients with compensated liver disease. Efficacy, defined by achieving sustained virologic response, is greater with the use of peginterferon-α2a compared to interferon-α2a. The recommended dose for the treatment of chronic hepatitis C in monotherapy and in combination therapy with ribavirin is 180 μg subcutaneously weekly. The side-effect profile is similar to that of interferon-α2a.

Peginterferon-α2b

Peginterferon-α2b is a covalent conjugate of interferon-α2b and monomethoxypolyethylene glycol (PEG). Its use is indicated for the treatment of chronic hepatitis C, as monotherapy and in combination with ribavirin in patients with compensated liver disease. Virologic response rates are superior with the use of peginterferon-α2b compared to interferon-α2b in patients with hepatitis C genotype 1. The superiority is less clear in the treatment of other hepatitis C genotypes. When used as monotherapy, the recommended dose is 1.0 μg/kg/week, subcutaneously. When used in combination with ribavirin, peginterferon-α2b is dosed 1.5 μg/kg/week. The side-effect profile is similar to that of interferon-α2b with the exception of a higher incidence of injection site reactions/inflammation with the pegylated agent.

LAMIVUDINE

Lamivudine is a pyrimidine analog most commonly used as part of combination regimens for treatment of HIV-1 infection. Lamivudine also inhibits hepatitis B DNA polymerase and may be used as treatment for chronic hepatitis B infection. Treatment with 100 mg daily has been shown to result in serologic conversion, virologic response, and histologic improvement. Treatment has been associated with the development of lamivudine-resistant mutants. Treatment of HIV-1-positive patients with lamivudine alone is not recommended because it is likely to result in rapid appearance of lamivudine-resistant HIV-1 strains. Lactic acidosis with severe hepatomegaly and steatosis are rare side effects of lamivudine. The majority of lamivudine is excreted unchanged in the urine.

Pharmacokinetics

Lamivudine is rapidly absorbed after oral intake. It is phosphorylated intracellularly. The incorporation of monophosphorylated lamivudine into viral DNA by HBV polymerase causes chain termination. The majority of lamivudine is eliminated unchanged in the urine. The mean elimination half-life is between 5 and 7 hours. Dose adjustment is necessary in patients with impaired renal function.

Adverse events

Serious adverse events reported with the use of lamivudine in patients with chronic hepatitis B infection include lactic acidosis, hepatic steatosis, pancreatitis, and post-treatment exacerbation of hepatitis B.

Drug interactions

As lamivudine is mainly eliminated by active organic cationic secretion into the urine, the possibility exists of interactions with other drugs eliminated by a similar mechanism. However, no clinically relevant interactions are known that would require dose adjustments.

OSELTAMIVIR

Oseltamivir phosphate is a neuraminidase inhibitor. It is indicated for the treatment of uncomplicated influenza in patients at least 1 year old. It is also indicated for the prophylaxis of influenza in

this same population. By inhibiting influenza virus neuraminidase, it is believed to alter viral particle aggregation and release. For the treatment of influenza in adults and adolescents, oseltamivir is dosed 75 mg twice daily for 5 days. Treatment should be started within the first 2 days of the commencement of symptoms. For prophylaxis of influenza, oseltamivir should be prescribed 75 mg once daily for a minimum of 7 days. The treatment should be started within 2 days of exposure.

Pharmacokinetics

Oseltamivir is absorbed by the GI tract and is converted to the carboxylate salt by hepatic esterases. Oseltamivir carboxylate is eliminated in the urine by both glomerular filtration and tubular secretion. The product package insert should be reviewed for information regarding plasma concentrations following various dosing schedules in renally impaired patients.

Drug interactions

Clinically significant drug interactions are unlikely to occur.

Common toxicities

Associated adverse events include GI upset, bronchitis, abdominal pain, dizziness, headache, insomnia, and fatigue.

PALIVIZUMAB

Palivizumab is a monoclonal antibody directed against the F protein of respiratory syncytial virus (RSV). It is used for the prevention of RSV infection in high-risk pediatric patients by passive immunization. Palivizumab is a "humanized" monoclonal antibody. It is produced in vitro and was developed using recombinant technology. It is genetically composed of 95% human and 5% murine sequences. It is administered as an IM injection at a dose of 15 mg/kg of body weight. Its efficacy has been demonstrated in children with bronchopulmonary dysplasia (BPD) and premature infants born at less than 35 weeks' gestation. Use of the monoclonal antibody resulted in a 55% decrease in the rate of hospitalization due to RSV infections. However, the severity of infection occurring despite prophylaxis did not appear to be significantly affected.

Pharmacokinetics and major toxicities

The mean half-life in pediatric patients was 20 days. Although no major toxicities have been observed, the potential for local and anaphylactic reactions may exist with this preparation, as with all protein injections.

PENCICLOVIR

Penciclovir is a nucleoside analog similar to ganciclovir in structure. It has activity similar to that of acyclovir and is available only as a topical preparation for recurrent herpes labialis. Famciclovir is an oral prodrug of penciclovir. In clinical trials, penciclovir shortened the duration of symptoms by half a day, if applied within 1 hour of the beginning of symptoms and again every 2 hours while awake. Thus, its unimpressive performance is similar to that of all topical preparations available for the treatment of herpes infections, other than in the eye.

RIBAVIRIN

Ribavirin is a synthetic nucleoside that interferes with viral RNA transcription, but its complete mechanism of action may be more complex. Ribavirin has a broad spectrum of activity against RNA viruses, including RSV, hepatitis C, measles virus, Lassa fever virus, and hantaviruses.

A major use for ribavirin is as combination therapy with interferon-α against chronic hepatitis C. Oral ribavirin combined with injected interferon-α (see below) has been shown to produce a sustained virologic response when used either as initial therapy or after relapse in patients previously treated with interferon-α alone. Oral dosage is based on body weight and is 400 mg in the morning and 600 mg in the evening daily for those weighing less than 75 kg. For those weighing more than 75 kg, the dosage is 600 mg twice a day. For previously untreated patients, treatment should be administered for 24 to 48 weeks. Discontinuation of therapy should be considered in those who have not responded by 24 weeks. For patients who have relapsed after interferon therapy, the recommended duration is 24 weeks. Ribavirin is administered as an aerosol for confirmed, severe, lower respiratory (RSV) infection in infants or the immunosuppressed adult host. Because ribavirin has in vitro activity against Lassa fever virus and hantaviruses, it has been used intravenously in Lassa fever cases, in hemorrhagic fevers, and in the recent hantavirus

pulmonary syndrome outbreak in the United States. Management of these rare and often fatal infections mandates contact with the Centers for Disease Control and Prevention (Atlanta, Georgia).

Pharmacokinetics

Ribavirin is rapidly absorbed after oral administration and undergoes first-pass metabolism. The elimination half-life of ribavirin is more than 300 hours after multiple dosing. Ribavirin thus accumulates over the long term in vivo. Aerosolized ribavirin is absorbed systemically with a plasma half-life greater than 9 hours.

Major toxicities

Ribavirin is potentially mutagenic, teratogenic, and embryotoxic. Documentation that a female patient is not pregnant and two methods of contraception while receiving therapy and for 6 months after treatment is therefore recommended. It is also recommended that similar precautions be observed if the male partner is being treated. Hematologic side effects, principally hemolytic anemia, are common, and the recommendations for dosage adjustment and discontinuation vary depending on whether the patient has known cardiac disease. Ribavirin by the aerosol route may lead to respiratory failure in chronic obstructive pulmonary disease (COPD) and asthma. Of note, the drug may precipitate in the mechanical ventilator and lead to an inability to ventilate the patient.

Drug interactions

It is not recommended to coadminister didanosine with ribavirin due to increased exposure to didanosine.

RIMANTADINE

Rimantadine hydrochloride (α-methyltricyclo-[3.3.1.1/3.7]decane-1-methenamine hydrochloride) is a structural analog of amantidine. It has essentially the same indications as amantadine, the prevention and treatment of influenza A. Similar to amantadine, due to widespread resistance among circulating influenza A strains, rimantadine is no longer recommended for the prevention or treatment of influenza.

TELAPREVIR

Telaprevir is a DAA that inhibits the NS3/4A serine protease of HCV. It is indicated for patients with compensated liver disease, including cirrhosis, who are previously untreated or who have failed previous interferon and ribavirin therapy, including prior null responders, partial responders, and relapsers. The treatment regimen is telaprevir 750 mg three times daily with food coadministered with peginterferon alfa and ribavirin for 12 weeks, followed by a response-guided regimen of either 12 or 36 additional weeks of peginterferon alfa and ribavirin depending on viral response and prior response status. HCV RNA should be monitored regularly as an inadequate viral response could lead to the development of resistance. Therefore, treatment discontinuation is recommended when HCV RNA levels exceed 1000 IU/mL at week 4 or 12, or upon confirmed detectable HCV RNA levels at week 24.

Pharmacokinetics

Telaprevir binds primarily to alpha 1-acid glycoprotein and albumin in a concentration-dependent manner. It is primarily metabolized by CYP3A but aldo-keto reductases and other non-CYP enzymes may also be involved.

Major toxicities

The most common adverse events associated with telaprevir are rash, pruritus, anemia, nausea, hemorrhoids, diarrhea, anorectal discomfort, dysgeusia, fatigue, vomiting, and anal pruritus. Telaprevir is associated with hypersensitivity including Stevens–Johnson syndrome (SJS), drug reaction with eosinophilia and systemic symptoms (DRESS), and toxic epidermal necrolysis (TEN). Fatal cases have been reported in patients with progressive rash and systemic symptoms who continued to treatment with telaprevir after a serious skin reaction was identified, therefore serious skin reactions, including rash with systemic symptoms or a progressive severe rash, warrant immediate discontinuation of peginterferon alfa, ribavirin, and telaprevir; discontinuation of other medications known to be associated with serious skin reactions should be considered. Patients should be promptly referred for urgent medical care.

Drug interactions

Telaprevir is a substrate and potent inhibitor of CYP3A and P-glycoprotein. Coadministration of telaprevir with alfuzosin, cisapride, pimozide,

rifampin, St. John's wort (*Hypericum perforatum*), ergot derivatives (i.e., dihydroergotamine, ergonovine, ergotamine, or methylergonovine), certain HMG-CoA reductase inhibitors (i.e., lovastatin or simvastatin), certain phosphodiesterase type 5 inhibitors when used in the treatment of pulmonary hypertension (i.e., sildenafil and tadalafil), or certain sedative/hypnotics (i.e., oral midazolam or triazolam) is contraindicated. It is not recommended to coadminister telaprevir and the following medications: rifabutin, salmeterol, certain corticosteroids (i.e., fluticasone, budesonide, prednisone, or methylprednisolone), and certain HIV protease inhibitors (i.e., darunavir/ritonavir, fosamprenavir/ritonavir, or lopinavir/ritonavir). The dose of colchicine or phosphodiesterase type 5 inhibitor when used for erectile dysfunction (e.g., sildenafil, tadalafil, or vardenafil) should be adjusted when coadministered with telaprevir.

TELBIVUDINE

Telbivudine is a nucleoside analog with activity against HBV DNA polymerase. It is indicated for the treatment of chronic hepatitis B infection in adult patients with evidence of viral replication and either persistently elevated aminotransaminases or histologically active disease. The recommended dosage is 600 mg once daily. The optimal duration of treatment has not yet been determined.

Pharmacokinetics

Telbivudine is phosphorylated by cellular kinases to the active triphosphate form (telbivudine 5′-triphosphate), which competes with thymidine 5′-triphosphate. When telbivudine 5′-triphosphate is incorporated by the viral DNA, it causes chain termination. Telbivudine is primarily eliminated by renal excretion as unchanged drug. Patients with moderate to severe renal impairment require modification of the dosing interval.

Adverse events

In clinical studies, telbivudine was well tolerated. However, lactic acidosis and severe hepatomegaly with steatosis have been reported. Severe exacerbations of hepatitis can occur after discontinuing therapy with telbivudine. No teratogenic toxicity has been seen in animal studies.

Drug interactions

No clinically remarkable drug–drug interactions are known.

TENOFOVIR

Tenofovir disoproxil fumarate is a nucleotide analog that inhibits reverse transcriptase. Tenofovir is indicated for the treatment of chronic hepatitis B infection and is commonly used for the prevention and treatment of HIV. The recommended dose of tenofovir disoproxil fumarate is 300 mg (245 mg tenofovir disoproxil) daily.

Pharmacokinetics

Following oral intake, tenofovir disoproxil fumarate is readily converted to tenofovir. It is renally excreted by both glomerular filtration and tubular secretion. The dosing interval should be adjusted in patients with renal impairment.

Major toxicities

Associated adverse events include asthenia, headache, abdominal pain, GI upset, pruritus, lactic acidosis, hepatitis, hepatomegaly with steatosis, and nephrotoxicity with prolonged use. An exacerbation of hepatitis can occur when treatment is discontinued.

Drug interactions

Tenofovir may potentiate or be potentiated by drugs that decrease renal function or compete for active tubular secretion.

TRIFLURIDINE

Trifluridine (trifluorothymidine) is a fluorinated pyrimidine analog that interferes with DNA synthesis and is used topically for the treatment of HSV keratitis. Trifluridine may cause local irritation and palpebral edema.

VALACYCLOVIR

Valacyclovir is a valyl ester of acyclovir that is metabolized to acyclovir after oral administration, resulting in plasma levels of acyclovir similar to those achieved with IV acyclovir. However, such higher bioavailability is expected to be dependent on factors such as GI absorption and hepatic function. Valacyclovir given at a dosage

of 1 g three times daily has been shown to reduce time to healing and postherpetic neuralgia in herpes zoster and to do so more effectively than acyclovir. Valacyclovir may also be used in primary (1 g twice daily for 10 days) and recurrent (500 mg three times per day) genital herpes. In patients with normal immune function, valacyclovir 1 g daily can be used as suppressive therapy of recurrent genital herpes. Herpes labialis can be treated with valacyclovir 2 g every 12 hours for 1 day. In most respects, valacyclovir is appropriate when oral acyclovir is used and may be a potential substitute for IV acyclovir. However, the exact situations in which oral valacyclovir may be safely substituted for IV acyclovir, especially in the immunosuppressed patient, remain to be defined.

Pharmacokinetics

Valacyclovir is readily absorbed from the GI tract after oral intake and is almost completely converted to acyclovir and L-valine via first-pass intestinal and/or hepatic metabolism. Acyclovir is primarily excreted in the urine.

Major toxicities

The major toxicities are similar to those of acyclovir.

Drug interactions

There are no known clinically significant drug–drug interactions. Probenecid coadministration does result in an increase of the acyclovir Cmax and area under the curve but are of doubtful clinical relevance.

VALGANCICLOVIR

Valganciclovir hydrochloride is a nucleoside analog and is the prodrug of ganciclovir. After oral administration, valganciclovir is rapidly converted to ganciclovir by hepatic and intestinal esterases. The active metabolite, ganciclovir triphosphate, is formed by phosphorylation by both viral and cellular kinases. Ganciclovir triphosphate is virustatic, by inhibiting viral DNA synthesis.

Valganciclovir is indicated for the treatment of AIDS-related CMV retinitis and for the prevention of CMV disease in high-risk recipients of kidney, heart, and kidney–pancreas transplants. It is commonly used for the prevention of CMV disease in HIV-1-infected patients who are felt to be at high risk for CMV disease because of a severely impaired immune system (most often determined by a very low CD4 lymphocyte count). It has significant advantages over ganciclovir, as it is administered orally thereby avoiding the need for indwelling catheters. For treatment of active CMV retinitis, it is recommended to induce the patient with 900 mg twice daily for 21 days, followed by maintenance with 900 mg daily. Valganciclovir should be dosed with food. To prevent CMV disease in patients who have received a kidney, heart, or kidney–pancreas transplant, valganciclovir, 900 mg, should be dosed daily (with food) within 10 days of transplant until 100 days post-transplantation.

Pharmacokinetics

Valganciclovir is well absorbed from the GI tract and is rapidly hydrolyzed to ganciclovir in the intestinal wall and in the liver. The major route of elimination is by renal excretion through glomerular filtration and active tubular secretion. The terminal half-life following oral administration of valganciclovir is 4.08 hours in healthy or HIV/CMV-positive patients. The terminal half-life in transplant patients is 6.48 hours. Dose adjustment is necessary in patients with renal impairment.

Major toxicities

As for ganciclovir, the major toxicity of valganciclovir is hematologic, often causing anemia, neutropenia, and thrombocytopenia. Additional adverse effects associated with its use include GI upset, fever, headache, peripheral neuropathy, paresthesias, tremors, renal insufficiency, and infections. Valganciclovir may be teratogenic or embryotoxic in humans.

Drug interactions/precautions

The clinician should avoid coadministering other drugs with the potential to suppress the bone marrow. Caution should also be exercised when considering the coadministration of other agents with nephrotoxic potential. Probenecid causes increased levels of valganciclovir. An increased incidence of seizures has been noted with the concomitant use of imipenem and cisplatin.

VIDARABINE

Vidarabine (Ara-A, adenine arabinoside) is a purine analog made from *Streptomyces antibioticus* that inhibits viral DNA polymerases. It has been

supplanted by acyclovir because of the greater efficacy and lower toxicity of acyclovir in HSV and VZV infections. It was the first agent used against HSV encephalitis but has been made almost obsolete by acyclovir. Acyclovir-resistant strains of HSV and VZV are currently treated with foscarnet. Vidarabine is currently only used as an ointment for the treatment of herpetic keratitis caused by HSV-1 and HSV-2.

ZANAMIVIR

Zanamivir is a neuraminidase inhibitor that is indicated for the treatment of influenza A and influenza B in patients aged ≥7 years who have been symptomatic for no longer than 2 days. It is also indicated for the prophylaxis of influenza in patients who are at least 5 years old. It is not recommended for patients with underlying airway disease such as COPD or asthma. It is administered to the respiratory tract by oral inhalation. It has been proposed that the mechanism of action of zanamivir is through inhibition of influenza virus neuroaminidase with possible alteration of viral particle aggregation and release.

Zanamivir is dosed as two inhalations every 12 hours for 5 days for the treatment of influenza.

Pharmacokinetics

Between 4% and 17% of oral inhaled zanamivir is systemically absorbed. It is renally excreted unchanged. Unabsorbed drug is excreted fecally. The serum half-life is between 2.5 and 5.1 hours.

Common toxicities

The use of zanamivir can precipitate bronchospasm and decline in pulmonary function. Many of these cases have occurred in patients with underlying airway disease, such as asthma or COPD. Other common adverse events associated with its use are GI upset, sinusitis, dizziness, headache, bronchitis, cough, and allergic reactions (including oropharyngeal edema and rash).

Drug interactions

There are no clinically relevant known pharmacokinetic drug interactions.

209. Probiotics

Varsha Gupta and Ritu Garg

Probiotics recently are defined as "live microorganisms which when administered in adequate amount confer a health benefit on the host" by the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO).

MECHANISM OF ACTION OF PROBIOTICS

- *Competitive exclusion of pathogenic bacteria*. Probiotics may compete with pathogenic bacteria for epithelial binding sites and thus prevent gut colonization by bacterial species such as *Clostridium difficile*, *Salmonella choleraesuis*, *Staphylococcus aureus*, and others.
- *Induction of defensin production*. Cytoprotective and antimicrobial substances are produced by the intestinal epithelium to control the microenvironment of the gut. Defensins are antimicrobial peptides synthesized by Paneth cells located in the crypts to counteract bacterial adherence and invasion.
- *Production of antibacterial substances*. Many lactic acid-producing bacteria (LAB) produce antibacterial peptides called bacteriocins, such as lactacin B from *Lactobacillus acidophilus*, having a narrow activity spectrum acting only against closely related bacteria.
- *Improved intestinal barrier function*. Recent data indicate that probiotics may initiate repair of the barrier function after damage.
- *Modulation of host immune functions*. Probiotic bacteria may act through the stimulation of Toll-like receptors (TLRs) and it appears that certain effects exerted by some probiotic strains or preparations are mediated through interactions with distinct TLRs. It can be assumed that probiotic bacteria stimulate dendritic cells which in turn produce anti-inflammatory cytokines.

An ideal probiotic preparation should harbor the characteristics mentioned in Table 209.1. For an adequate amount of health benefits, a dose of 5 billion colony-forming units (CFU) a day (5×10^9 CFU/day), for at least 5 days, has been recommended. Bacteria and yeasts may be used as probiotics either in the form of a single strain or combination of microorganisms or mixed with prebiotics (Table 209.2).

Table 209.1 The characteristics of an ideal probiotic preparation

- It should have high cell viability, thus should be resistant to low pH and acids
- It should have the ability to persist in the intestine, even if the probiotic strain cannot colonize the gut
- It should be adhesive to the gut epithelium, so that it can cancel the flushing effects of peristalsis
- It should be able to interact or send signals to the immune cells associated with the gut and influence local metabolic activity
- It should be of human origin
- It should be nonpathogenic, nontoxic, free of serious side effects
- It should be resistant to processing and be present in the product in an adequate number of viable cells to confer the health benefit

Table 209.2 List of microbes being used in probiotic preparation

Genus	Species
Lactobacillus	*L. acidophilus, L. casei, L. fermentum, L. gasseri, L. johnsonii, L. lactis, L. paracasei, L. plantarum, L. reuteri, L. rhamnosus GG, L. salivarius, L. bulgaricus, L. sporogenes, L. delbrueckii, L. brevis, L. cellobiosus, L. helveticus, L. crispatus, L. delbrueckii* subsp. *lactis, L. salivarius* subsp. *salicinius*
Bifidobacterium	*B. bifidum, B. breve, B. lactis, B. longum, B. infantis, B. thermophilum, B. animalis, B. adolescentis*
Streptococcus	*S. thermophilus, S. salivarius, S. lactis, S. cremoris, S. intermedius*
Saccharomyces	*S. boulardii, S. cerevisiae*
Other	*Bacillus cereus, Escherichia coli, Enterococcus faecalis, Enterococcus faecium, Propionibacterium, Leuconostoc, Pediococcus, Aspergillus niger, Aspergillus oryzae, Candida pintolopesii*

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

APPLICATIONS OF PROBIOTICS FOR HUMAN USE

Evidences of probiotic effectiveness in necrotizing enterocolitis (NE)

NE is one devastating intestinal disorder that a preterm infant may face in a neonatal intensive care unit (NICU). Low-birth-weight preterm infants delivered by cesarean section often require intensive care and are breastfed only after several days. The normal process by which microorganisms, such as lactobacilli, are ingested via vaginal birth and propagated by the mother's milk does not take place in these infants. A human trial with 2.5×10^8 CFU of live *Lactobacillus acidophilus* and 2.5×10^8 CFU of live *Bifidobacterium infantis* given to 1237 newborns in Columbia resulted in 60% reduction in NE and overall mortality.

Diarrhea

Probiotics can prevent or ameliorate diarrhea through their effects on the immune system. Moreover, probiotics might prevent infection because they compete with pathogenic viruses or bacteria for binding sites on epithelial cells. Probiotics might also inhibit the growth of pathogenic bacteria by producing bacteriocins. A Cochrane review on the efficacy of probiotics for treating infectious diarrhoea, including both adults and children, evaluated 63 studies with a total of 8014 participants. No adverse events were attributed to probiotic intervention. The use of probiotics reduced the duration of diarrhoea, although the size of the effect varied considerably between studies. Probiotics have preventive as well as curative effects on several types of diarrhea of different etiologies.

There is ample evidence that probiotics reduce the duration and severity of rotavirus diarrhea.

At least two systematic reviews suggest that probiotics, including various bacterial species and the yeast *Saccharomyces boulardii*, effectively reduce the incidence of diarrhea in patients who are taking antibiotics (antibiotic-associated diarrhea [AAD]). While research using probiotics has extended to a vast array of diseases, the most investigated field continues to remain infectious diarrhea.

Helicobacter pylori infection

H. pylori is a major cause of chronic gastritis and peptic ulcer and a risk factor for gastric malignancies. Antibiotics directed towards *H. pylori* eradication are 90% effective. However, these treatments are expensive and can cause side effects, along with antibiotic resistance. Probiotic treatment can also reduce the side effects associated with *H. pylori* therapy.

Constipation

In adults, data suggest a favorable effect of treatment with *Bifidobacterium lactis* DN-173 010, *Lactobacillus casei* Shirota, and *Escherichia coli* Nissle 1917 on the frequency of defecation and stool consistency.

Role in lactose intolerance

This condition results from an insufficient activity of the lactose-cleaving enzyme lactase (β-galactosidase) in the small intestine. The health effect associated with the consumption of fermented milk products is the enhancement of lactose digestion and avoidance of intolerance symptoms in lactose malabsorbers. Yoghurt commonly made from *Lactobacillus bulgaricus* and *Streptococcus salivarius* subsp. *thermophilus* is usually effective.

Inflammatory bowel disease (IBD)

Inflammatory bowel disease classically includes ulcerative colitis, Crohn's disease, and chronic pouchitis, representing different patterns of chronic inflammation of the gastrointestinal tract. Recent clinical and experimental observation implicates an imbalance in the intestinal mucosa with relative predominance of aggressive bacteria and relative paucity of protective bacteria and an increase in fungal and a decrease in methanogen diversity; also there is stimulation of proinflammatory immunologic mechanisms, based on the activation of the pattern recognition receptors in the gastrointestinal tract of IBD patients.

Various preliminary studies suggest a positive response to probiotics in patients with IBD and pouchitis.

Role in urogenital tract infections (UTIs)

The dominant presence of lactobacilli in the urogenital microbiota of healthy women and the obliteration of lactobacilli in patients who develop UTIs and many other genital infections has led to a focus on these bacteria. The concept of treating and preventing urogenital infections by instilling probiotic organisms has great appeal to

patients and caregivers. Hence, the administration of *Lactobacillus rhamnosus* GR-1 and *Lactobacillus fermentum* RC-14 as a therapy to restore and maintain urogenital health is a major step for prevention and treatment of urogenital infections.

Bacterial vaginosis (BV)

A growing body of evidence suggests that vaginal H_2O_2-producing lactobacilli may have a protective effect against urogenital infections, including UTI. It is hypothesized that lactobacilli prevent uropathogen colonization of the vagina, a necessary step in ascending infection of the bladder. BV can lead to complications in pregnancies, causing premature rupture of membranes, premature death, or the death of the fetus or newborn. Certain *Lactobacillus* strains, including *Lactobacillus crispatus* CTV05, *L. rhamnosus* GR-1, and *L. fermentum* RC-14, are able to remain in the vagina for several months after insertion.

Candidal vaginitis

The studies have shown a significant reduction in vaginal colonization with *Candida* after the oral administration of *L. acidophilus* and there was clinical improvement with a 7-day course of vaginal suppositories of *Lactobacillus rhamnosus* GG (LGG) in women with recurrent vaginitis.

Cancers

In intestinal tumors, prevention or delay of tumor development by lactobacilli is due to the binding to mutagenic compounds in the intestine and also suppressing the growth of bacteria which convert procarcinogens into carcinogens.

Respiratory infections

A meta-analysis that included ten randomized controlled trials (RCTs) comparing probiotics with placebo to prevent acute upper respiratory tract infections showed that probiotics were more effective than the placebo in reducing the number of participants experiencing episodes of acute upper respiratory tract infections, reducing the rate ratio of episodes of acute upper respiratory tract infections, and reducing antibiotic use.

A meta-analysis of five RCTs showed that the administration of probiotics is associated with lower incidence of ventilator-associated pneumonia compared with placebo.

Role in mucosal immunity

The gastrointestinal mucosa is the primary interface between the external environment and the immune system. In the complete absence of intestinal microbiota antigen transport is increased, indicating that the normal gut flora maintains gut defenses. Secretory immunoglobulin A (IgA) plays an important role in mucosal immunity, acting as a barrier against pathogenic bacteria and viruses. An increased IgA immune response has been noticed in children with Crohn's disease treated with LGG.

Role in allergy

The composition of the vaginal microbiota has been shown to influence the ultimate asthmatic condition of children. According to a double-blind, randomized, placebo-controlled trial LGG given to pregnant women for 4 weeks prior to delivery and then to newborn children at high risk of allergy for 6 months caused a significant reduction in early atopic disease. Other clinical studies showed that LGG and *B. lactis* BB-12 have been useful in infants allergic to cow's milk. There are studies to suggest probiotics might have a role in atopic rhinitis by reducing symptom severity and medication use.

Role in autoimmunity

Lactobacillus casei strain Shirota (LcS) induced recovery of host immune responses that were decreased by treatment with carcinogens and augmented the natural killer activity and T-cell functions of host immune cells. After LcS ingestion by the host, it is incorporated into M cells in Peyer's patches and digested to form active components. The results suggest that some probiotic bacteria have the potential to augment or modify the host immune function through the regulation of host immune cells.

Role of probiotics in lowering of serum cholesterol

Large dietary intake of yoghurt was found to lower dietary cholesterolemia, and the findings suggested that yoghurt contains a factor that inhibits the synthesis of cholesterol from acetate.

Improvement of hypertension

Probiotics have antihypertensive roles via the improvement and treatment of lipid profiles, modulation of insulin resistance and sensitivities,

the modulation of renin levels, and also the conversion of bioactive phytoestrogens as an alternative replacement of sexual hormones such as estrogen and progesterone.

Diabetes

It has been suggested that the consumption of probiotics can lower the onset of insulin resistance and consequently reduce the incidence of hypertensive conditions that are closely related to diabetes.

Obesity

One emerging finding has suggested that the gut microbiota has a role in the regulation of energy balance and weight. Future studies are needed to better understand the causal relationship between gut microbiota of varied composition and the propensity to be obese or lean and to assess whether modulating the gut microbiota could help reduce obesity.

Oral medicine and dentistry

Particular species of *Lactobacillus* and *Bifidobacterium* may exert beneficial effects in the oral cavity by inhibiting carcinogenic streptococci and *Candida* spp. *Lactobacillus reuteri* was efficacious in reducing both gingivitis and plaque in patients with moderate to severe gingivitis.

Antibacterial effects

In vitro studies suggest multiple specific activities of different probiotic agents against several pathogens, including *Listeria monocytogenes, Salmonella typhimurium, E. coli*, and *H. pylori* among others. Therefore, probiotic agents may provide prototypic antimicrobial substances that will be useful for pharmaceutical companies in the development of new antibiotics. Another field of interest for the researchers is to decrease antibiotic consumption and fight the negative effects of antibiotic use.

Probiotics in critical illness

Some studies propose that probiotics have an important emerging role in managing critical illnesses originating in the gastrointestinal tract, such as acute pancreatitis. In cirrhotic patients, probiotics have shown to decrease the incidence of encephalopathy. Reduction of post liver transplant infective complications using probiotics has also been reported.

Surgical infections

Before the advent of antiseptics and antibiotics, fermented milk was used for healing wounds and to fight infections. Recent studies show some success in the application of probiotics for treating and preventing surgical infections.

Effect on bones

Several studies in humans have shown positive effects of nondigestible oligosaccharides (NDO) on mineral absorption and metabolism, and bone composition and architecture. Synbiotics, i.e., a combination of probiotics and prebiotics, can induce additional effects. Proposed future applications include the treatment of rheumatoid arthritis, prevention of ethanol-induced liver disease, and prevention or treatment of graft-versus-host disease.

SAFETY ISSUES

Generally recognized as safe (GRAS) status is defined by the US Food and Drug Administration for food adjuncts that may not meet the usual requirements for safety assessment but have been used extensively without demonstrable harm. Probiotics are claimed to be GRAS as they comprise organisms identical to those in human gut and vaginal flora, although strain dependence needs to be considered and GRAS is only granted to one specific probiotic preparation used in one specific food product. Various studies conducted on *Lactobacillus* and *Bifidobacterium* species showed no adverse effects. In immunocompromised individuals, however, this might be different, especially in patients with severe underlying comorbidities.

The use of safety becomes more complicated if one considers organisms such as *Enterococcus* spp., *S. boulardii*, and *E. coli* as probiotics.

In order to establish safety guidelines for probiotic organisms, the FAO and the WHO recommended that probiotic strains should be characterized at a minimum with a series of tests, including antibiotic resistance patterns, metabolic activities, toxin production, hemolytic activity, infectivity in immunocompromised animal models, and side effects and adverse incidents in consumers.

CONCLUSION

In conclusion, studies done in humans suggest that probiotics have a considerable role to play for preventive or therapeutic applications in various diseases mainly related to the gastrointestinal tract, allergic disorders, and to some extent in the urogenital tract of humans. However, it is worth mentioning that many probiotic health claims have not yet been substantiated by thoroughly conducted experimental studies. We still need well-designed, placebo-controlled, sufficiently powered studies that will reflect the actual role of probiotics.

210. Hypersensitivity to antibiotics

D'Jahna Akinyemi, Gulfem E. Celik, and N. Franklin Adkinson, Jr.

Adverse drug reactions (ADRs) are usefully separated into type A reactions (predictable from known pharmacologic properties and largely dose related) and type B reactions (unpredictable and restricted to a vulnerable subpopulation). Type B reactions comprise 10% to 15% of all ADRs and include *immunologic drug reactions, drug intolerance* (e.g., tinnitus after single aspirin tablet), and *idiosyncratic reactions*, some of which are pseudoallergic (e.g., aspirin-induced reactions).

Immune mechanisms are thought to be involved in 6% to 10% of all ADRs. Allergenic drugs can induce the entire spectrum of immunopathologic reactions, which are clinically indistinguishable from reactions elicited by foreign macromolecules (Table 210.1). Gell and Coombs' type I reactions are caused by drug/antigen-specific immunoglobulin E (IgE) that binds to high-affinity Fc-IgE receptors on mast cells and basophils. Cross-linking of these receptors leads to the release of vasoactive mediators such as histamine and cysteinyl leukotrienes. Typical syndromes include urticaria, anaphylaxis, rhinitis, and bronchoconstriction, which can occur immediately in a previously sensitized individual. Type II cytolytic reactions are generally confined to rapidly haptenating drugs such as penicillins and are based on immunoglobulin G (IgG)-mediated cytotoxic mechanisms, resulting mainly in blood cell cytopenias. Type III reactions are immune complex mediated and may involve complement activation and stimulation of Fc-α receptor-activated inflammatory cells. Drug-specific immune complexes result from high-dose, prolonged therapy and may produce drug fever, a classic serum sickness syndrome, and various forms of cutaneous vasculitis. Type IV reactions are mediated by T lymphocytes and cause "delayed hypersensitivity reactions," the most typical examples being delayed maculopapular exanthem and contact dermatitis from topically applied drugs. Many drug-induced hypersensitivity reactions such as bullous, pustular, and some morbilliform skin eruptions that are presumed to have an immune etiology did not seem to fit into the older Gell and Coombs classification. Recent studies of T-cell subsets and functions in the pathogenesis of delayed-onset immune reactions have suggested subcategories of type IV reactions as shown in Table 210.1.

However, some drug reactions resemble allergic syndromes but are not immunologic in origin. These nonimmune hypersensitivity reactions are also known as "pseudoallergic reactions." Most pseudoallergic reactions mimic type 1 IgE-mediated reactions such as urticaria, angioedema, bronchospasm, and anaphylaxis. In such cases basophils and mast cells are activated by nonimmune mechanisms, and vasoactive mediators are released.

In this chapter, we review type B ADRs to antibiotics with a focus on current concepts in the diagnosis and management of allergies to β-lactam antibiotics, the prototype of immunologic drug allergies. We also address the management of multiple antibiotic sensitivity syndromes.

EPIDEMIOLOGY OF ANTIBIOTIC ALLERGY

β-Lactams and sulfonamides are the most prevalent causes of antibiotic hypersensitivity. In a cross-sectional survey of a general population from Porto, Portugal, history of hypersensitivity to penicillin and other β-lactam antibiotics was found in 4.5% of adults. In the United States, in recent large healthcare insurance database studies, history of hypersensitivity to penicillin was recorded in about 10% of patients. Data from developing countries are limited, but

Table 210.1 Features of immunopathologic reactions to antibiotics and management strategies

Reaction category	Clinical manifestation	Common examples for antibiotics	Timing for sensitization with the first use of the drug	Onset after re-exposure to the drug	Skin tests	In vitro tests	Readministration of the drug (DPT/ desensitization)
Type I (IgE)	Urticaria, angioedema, rhinitis, bronchospasm, anaphylaxis	β-lactam antibiotics Sulfamethoxazole	Required: 1–2 wk	Usually within 1 h (rarely after hours)	Immediate (wheal/ flare)[a] Intradermal tests	RAST (serum IgE) Serum mast cell tryptase level Basophil activation	Desensitization if skin test +
Type II (IgG and complement)	Hemolytic anemia, drug-induced nephritis, thrombocytopenia, neutropenia	Penicillins Cephalosporins Sulfonamides	Required: 1–2 wk	Many days or weeks	None	Complete blood count Coombs tests	Cautious DPT
Type III (IgG immune complexes)	Serum sickness, fever, vasculitis	Penicillins Cephalosporins Sulfonamides Streptomycin	Required: 10–21 d	Usually days to weeks	None	ESR CRP Immune complex Serum complement levels	Cautious DPT
Type IVa (Th1 lymphocytes)	Allergic contact dermatitis	Penicillins Neomycin Bactrim	Required: 1–3 wk	8–120 h	Patch tests Intradermal tests (delayed response at 48–72 h)	Lymphocyte transformation tests	Likely contraindicated
Type IVb (Th2 lymphocytes)	Maculopapular eruptions	Penicillins, especially diaminopenicillins like amoxicillin and ampicillin Sulfonamides	Required: 4–14 d		Patch tests Intradermal tests (delayed response at 48–72 h)	Lymphocyte transformation tests[b]	DPT useful
Type IVc cytotoxic lymph. (perforin/ granzyme B)	Contact dermatitis, maculopapular and bullous exanthema, hepatitis, SJS, TEN	Sulfonamides Penicillins Macrolides	Required: 1–2 wk		Patch tests Intradermal tests (delayed response at 48–72 h)	Lymphocyte transformation tests[b]	Contraindicated (for bullous exanthem and SJS/TEN)
Nonimmunologic	Urticaria, angioedema, rhinitis, erythema bronchospasm	Vancomycin (red man syndrome)	Not required Reaction may occur with first dose	Within minutes, infusion rate dependent	None	None	Slow infusion Use premedication

Abbrevations: DPT = drug provocation tests; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; RAST = radioallergosorbent test; IgE = immunoglobulin E; IgG = immunoglobulin G; SJS = Stevens–Johnson syndrome; TEN = toxic epidermal necrolysis.

[a] Only validated for penicillin skin testing, which has high negative predictive value. Positivity may be helpful with certain antibiotics; however, negative skin tests do not exclude the diagnosis for many immediate reactions to antibiotics.

[b] Clinically false positivity may occur.

According to Gell and Coombs, as modified.

Table 210.2 Relative risks of immunologic reactions to commonly used antibiotics

Risk of inducing an immunologic reaction[a]	Antibiotic (or its class)
Common (>2%)	Penicillins Antimicrobial sulfonamides Nitrofurantoin
Intermediate (0.1%–2%)	Bacitracin Cephalosporins Penems Itraconazole Quinolones Minocycline
Rare (0.1%)	Monobactam (aztreonam) Aminoglycosides Amphotericin B Chloramphenicol Clindamycin Fluconazole Griseofulvin Ketoconazole Macrolide antibiotics Vancomycin Tetracyclines Polymyxin Metronidazole

[a] Among patients receiving multiple courses of therapy.

suggest that penicillin allergy is the most commonly reported antibiotic allergy. History of hypersensitivity to sulfonamides has been reported to occur in 2% to 4% of populations, but is increased among acquired immunodeficiency syndrome (AIDS) patients to 40% to 80%. Immunologic reactions to the newer classes of antibiotics are often rare and poorly documented. The perceived relative risk of immunologic drug reactions with commonly used antibiotics is given in Table 210.2.

BURDEN OF ANTIBIOTIC ALLERGY

β-Lactams are among the most commonly prescribed antibiotics for treatment of many types of bacterial infections. However, recent data show a significant decrease in β-lactam prescriptions, in part due to a rising prevalence of histories of allergy, which can exceed 30% in intensive care environments. Emergence of bacterial resistance as well as introduction of newer antibiotics have also contributed to this trend. Prescriptions of quinolones and macrolides as alternative antibiotics for common infections have been increasing as has the use of vancomycin in patients with histories of penicillin allergy, yet only 10% to 15% of the subjects with a history of penicillin reactions have positive type I skin tests. Unevaluated histories of antibiotic allergies may lead to the substitution of often less effective or more toxic, and more expensive, alternative drugs, which can result in high medical and economic burdens on health care. In a retrospective study of hospital practice, penicillin-allergic patients had higher antibiotic costs and were more likely to receive a broader-spectrum antibiotic such as cephalosporins, macrolides, and quinolones. At the Mayo Clinic, prophylactic vancomycin use in patients with a history of penicillin or cephalosporin allergy undergoing elective orthopedic surgery was substantially reduced by targeted allergy consultation and penicillin allergy skin testing. Similar benefits are likely to occur in patients with histories of other antibiotic allergies who are appropriately evaluated before alternative antibiotics are selected.

CLINICAL FEATURES

The presentation of antibiotic allergies is similar to known hypersensitivity reactions, and the clinical features are variable depending on the type and severity of the reaction and the organ systems affected (Table 210.1). Many factors such as the immunologic profile of the antibiotic; treatment factors, including dosage, administration route, and frequency; host factors such as immune status and comorbidities; and the inflammatory milieu in which antibiotics are used can influence the frequency and characteristics of hypersensitivity reactions.

The skin is the most common organ involved in antibiotic reactions. Maculopapular eruptions (MPEs), urticaria, and pruritus are the most common presentations that typically occur after hours, days, or even weeks of antibiotic exposure but can also be part of an acute allergic reaction. Immunologic drug reactions require a sensitization period, whereas a nonimmunologic mast cell release can occur on first exposure in susceptible patients. Antibiotics can also cause severe but rare exfoliative skin syndromes such as toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS). Other targeted organ manifestations such as interstitial pneumonitis and immune cytopenias are rare. Life-threatening reactions such as anaphylaxis are also rare. Although β-lactams are the most

Table 210.3 Clinical features of hypersensitivity reactions

Antibiotic	Common	Less common/rare
β-lactams	Urticaria, MPE	Exfoliative dermatitis, TEN, SJS, serum sickness syndrome, vasculitis, cytopenias, anaphylaxis, nephritis
Sulfonamide	Fixed drug eruption HIV(+): delayed MPE+fever, urticaria, angioedema	Erythema multiforme, SJS, TEN Anaphylactic reactions
Quinolones	Urticaria, FDE, photoallergic reactions	Acute interstitial nephritis, acute hepatitis, serum sickness, SJS, TEN, MPE, acute pancreatitis, anemia; thrombocytopenia
Macrolides	Urticaria, angioedema, FDE, and MPE	TEN, vasculitis
Vancomycin	"Red man syndrome," lineary IgA bullous dermatosis	MPE, FDE, vasculitis, thrombocytopenia, erythema multiforme, and urticaria anaphylaxis

Abbrevations: FDE = fixed drug eruptions; MPE = maculopapular eruption; TEN = toxic epidermal necrolysis; SJS = Stevens–Johnson syndrome; IgA = immunoglobulin A; HIV = human immunodeficiency virus.

common antibiotic class inducing anaphylaxis, IgE antibody responses have also been documented for sulfonamides; those now in use are given in Table 210.3.

CLINICAL ASSESSMENT

Drug allergy syndromes are recognized by the constellation of signs and symptoms identified with a particular mechanism of immunopathology (Table 210.1). Appropriate diagnosis of these cases depends largely on careful history taking, with attention to prior drug experience and the chronology of the reaction, supplemented by compatible physical and laboratory findings, and knowledge of drug allergenicity profiles. For atypical or discordant reactions, skepticism is appropriate to avoid labeling the patient as "drug allergic" incorrectly.

Step 1: initial evaluation

HISTORY TAKING

A detailed history is essential for the initial evaluation of patients with suspected drug allergies. The history guides a decision about performing further diagnostic testing and other evaluation strategies. It is also possible to make a reasonable decision about risks of reintroduction of the suspected drug by using historical detail. Medical records that describe previous reactions and treatment can be very helpful, especially in patients with vague histories or altered mental status. Occasionally, information provided by a relative or friend who witnessed the event can also be very helpful in differential diagnosis.

The clinical history of suspected drug allergy should be focused on both medication-related and patient-related factors. The medication(s) implicated, clinical features of the reaction(s), and the previous exposure and reaction to each drug and related compounds as well as comorbid disorders of the patients should be recorded. For example, patients with chronic urticaria often attribute cutaneous reactions to drugs and foods. Similarly symptoms of chest tightness or pain, dyspnea, and tachycardia after use of a drug can be a sign of underlying cardiovascular disease. Other patient comorbidities include the high frequency of amoxicillin-induced morbilliform rashes in patients with mononucleosis, and frequent trimethoprim–sulfamethoxazole reactions in AIDS patients. Another example is that patients with cystic fibrosis have a higher risk for immune reactions to antibiotics, probably because of frequent re-exposure.

History taking provides information helpful in assessing the likelihood of immune mediation. Immunologic reactions require a sensitization period, so putatively allergic patients should have a history of prior use of either the drug itself or a structurally related compound. For first drug exposure, an immunologic reaction may be seen after 3 to 10 days, which can be sufficient for primary sensitization. Nonimmunologic reactions do not require sensitization, and reactions may be seen even after the first dose. Pseudoallergic reactions can often be distinguished from IgE-mediated reactions with similar clinical manifestations by reliable histories of previous drug use. Based on clinical features and the chronology of the reaction, conclusions can often be drawn

about whether a reaction is immunologically mediated (Table 210.1).

PHYSICAL EXAMINATION

Direct observation of patients undergoing presumed drug reactions can be useful for both differential diagnosis and objective assessment of severity, which can often be exaggerated in retrospective patient accounts. A complete physical examination is desirable as many organ systems have the potential for involvement. For skin reactions occurring with drug use, a detailed dermatologic examination is often helpful. Viral exanthems are easily confused with maculopapular drug eruptions. Fever and coryza or pharyngitis can help to identify the former.

Step 2: decision about application of further diagnostic testing

History alone is often not sufficient for establishing current drug sensitivity. Only 10% to 15% of subjects with a convincing history of IgE-dependent penicillin allergy will be positive by validated skin testing, indicating a very low diagnostic accuracy of history alone for current sensitivity. Data with other drugs are similar, suggesting that sensitivity may wane with time. Drug provocation tests that are the gold standard for the diagnosis of current drug allergy have a similarly low positivity rate in patients with history of drug allergy. These data indicate that diagnosis of current sensitivity based on history alone is often not advisable. Further diagnostic tests for definite diagnosis may be needed.

Unfortunately, many in vivo and in vitro diagnostic tests for allergy have shown limited value in the diagnosis of allergy to haptenic (small molecular weight) drugs.

Although skin testing provides valuable information for the diagnosis of immediate reactions to penicillins and in some cases to other β-lactams, the validity of skin tests with other antibiotics is limited as the antigenic determinants are not adequately known. In vitro tests for drug-specific IgE to antibiotics are of limited value because they are less sensitive than intradermal tests. A positive result, however, is usually reliable and corresponds to skin test results. If there is no contraindication, drug provocation testing with the offending drug is the most reliable test for diagnosis of current antibiotic hypersensitivity for many haptenic drug allergies. Because such testing carries some risk for the patient, its use is usually restricted to cases where alternative antibiotics are unacceptable or there are multiple antibiotic sensitivities. A stepwise approach to the diagnosis of antibiotic allergy is given in Figure 210.1. Diagnostic testing can be pursued based on likely immunopathology as given in Table 210.1.

EVALUATION OF IMMEDIATE-TYPE SENSITIVITIES

Skin testing for β-lactam antibiotics

Intradermal skin testing with a 15- to 20-minute readout of wheal and flare has been validated for detecting drug-specific IgE antibodies to penicillins and other β-lactam antibiotics. A major determinant analog (*penicilloyl-polylysine*) and minor determinants (*benzylpenicilloate*, *benzylpenilloate*, and *benzylpenicillin* isomers of penicillin) are used for skin test evaluation for IgE-dependent penicillin allergy. IgE antibodies to minor determinants are clinically associated with anaphylactic reactions and can predict the risk of more severe reactions. IgE antibodies to the major penicilloyl determinant correlate loosely with risk for urticarial reactions.

Testing is undertaken with two or more reagents, usually penicilloyl–polylysine (PrePen) antigen and either penicillin alone (10 000 IU/mL) or a mixture of minor antigens, including at least benzylpenicillin and benzylpenicilloate (10 mM each). Of these minor determinants, only benzylpenicillin is available commercially in the United States. Skin prick testing with full-strength reagents is done first, and if these tests are negative at 15 minutes, they are followed by intracutaneous testing, raising an initial bleb of 2 to 3 mm. A wheal diameter of least 3 mm greater than negative control is considered positive. In some centers, elective testing is followed by the administration of one to three doses of oral penicillin and a period of observation to confirm that the drug is tolerated. For hospitalized patients with serious infection, a rapid dose escalation of the intravenous antibiotic of choice is judiciously employed.

Falsely negative penicillin skin testing is rare, and all reports are of mild, self-limited, and/or transient reactions. About 85% to 90% of history-positive patients will have negative penicillin

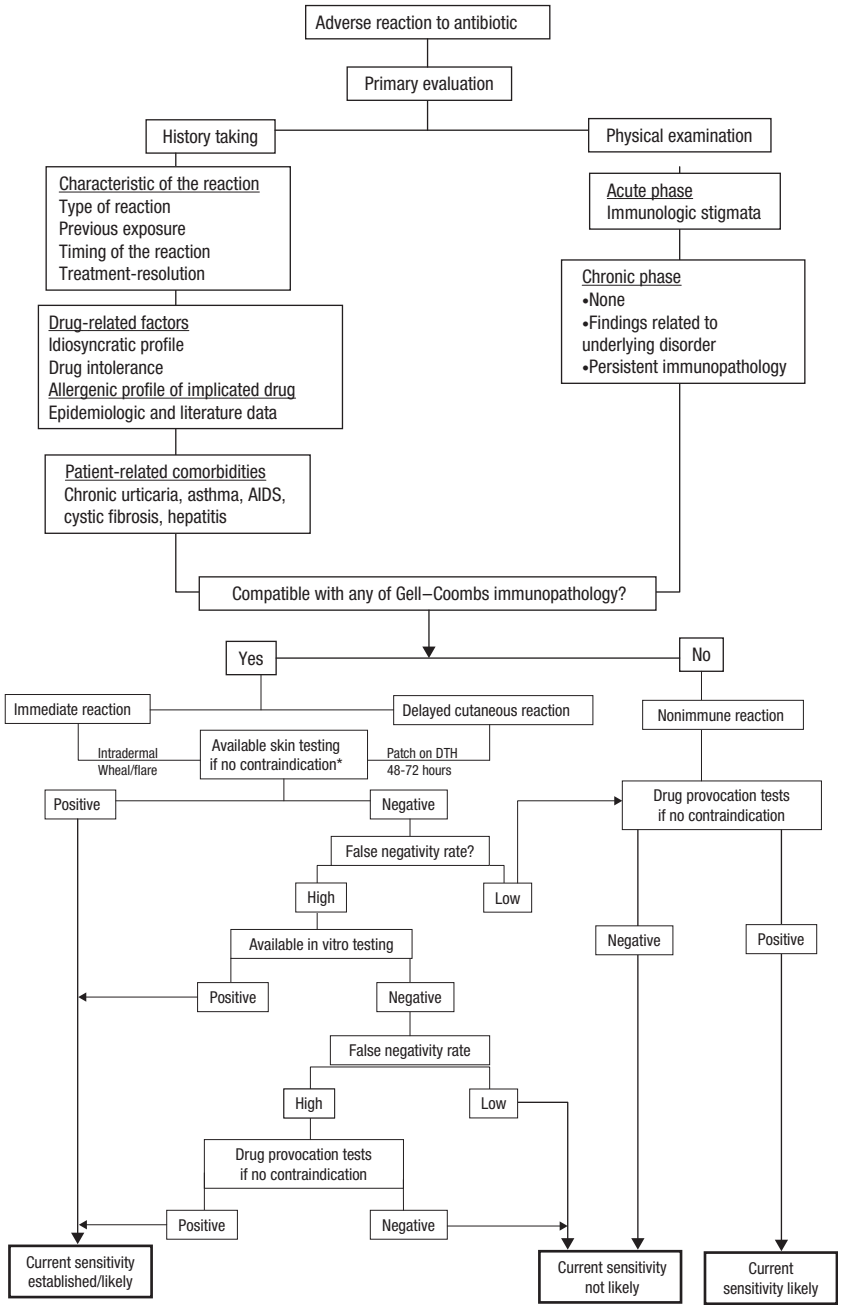

Figure 210.1
A diagnostic algorithm for evaluation of putative immunologic reactions to antibiotics. *Contraindications for skin immunoglobulin E testing are extensive skin lesion, recent antihistamine use, and history of serious immediate systemic reaction with allergen exposure. AIDS = acquired immunodeficiency syndrome; DTH = delayed-type hypersensitivity.

testing, allowing a large majority of such patients to be retreated safely. Despite this substantial diagnostic power, it has been difficult to maintain persistent commercial sources for these reagents in the United States and Europe. Some academic centers have produced the reagents for their own use, but concerns persist about access to these orphan drug products.

Recent studies show promising results with cephalosporin skin tests. Concentrations of 2 to 3 mg/mL of a parenteral cephalosporin preparation are reported to be usually nonirritating, but each cephalosporin requires concurrent evaluation for its irritant potential in nonallergic subjects. Although a positive cephalosporin skin test implies the presence of drug-specific

IgE antibodies, a negative test does not exclude immediate hypersensitivity.

Commercial cephalosporin skin test reagents are not currently available in the United States. Positive intradermal skin tests have been reported for imipenem and other β-lactams, but validated skin testing protocols have not been developed.

In vitro tests

Specific IgE tests have been established for a wide variety of immediate-type drug allergies. Only with penicillin allergy have in vitro test results been systematically compared with skin tests. The consistent finding has been diagnostic sensitivity for penicilloyl–IgE by radioallergosorbent test (RAST) of 65% to 85% compared with penicilloyl–polylysine skin tests and 32% to 50% compared with a combination of skin testing and challenge. Minor determinant penicillin IgE antibodies are not reliably detected by available immunoassays. In recent years, flow cytometry has been increasingly used in the diagnosis of allergy. Assessment of basophil activation by means of increase in surface markers such as CD63 has been investigated in penicillin allergy. In one study from Europe, sensitivity was $\leq$30% compared with a diagnosis confirmed by skin testing. As with unvalidated skin tests, a clearly positive result is of greater clinical value than a negative result, thus in vitro basophil activation tests remain investigational.

EVALUATION OF NONIMMEDIATE REACTIONS

Skin testing

European studies suggest that both patch tests and intradermal tests with delayed cutaneous readouts (at 48 and 72 hours) are useful in evaluating nonimmediate reactions to aminopenicillins and certain β-lactams and that both can reliably predict the results of rechallenge. Additional studies are required to confirm and extend these results to other drug allergies and to define more precisely the clinical correlation and predictive value for retreatment.

Other tests

Drug-specific T lymphocytes, which are involved in some cutaneous hypersensitivity reactions, may be detected with the use of in vitro lymphocyte transformation tests, which are utilized in Europe but not approved for diagnostic use in the United States. However, sensitization may be found after recent treatment even in the absence of any clinical reactivity, and positive test results have been demonstrated after both immediate and delayed antibiotic-induced reactions caused by β-lactam antibiotics, sulfonamides, and quinolones. Cytokine detection assays are also available to evaluate delayed-type hypersensitivity drug reactions, but are still investigational.

USE OF DRUG PROVOCATION TESTS

Definitive diagnosis of drug allergy involves provocation testing as the last step, during which gradually increasing doses of the offending drug are given. Provocation testing may be necessary to accurately identify the responsible agent when multiple drugs are given simultaneously and a reaction occurs. It is particularly important not to incorrectly label a patient allergic to an antibiotic because it may severely restrict antibiotic choices for life.

Studies indicate that only a small minority of history-positive subjects have positive drug challenges. Drug provocation tests should be considered only after evaluating the risk–benefit ratio for an individual patient, and should be performed by experienced personnel in an appropriate environment. Informed consent of the patient should be obtained prior to the procedure.

MANAGEMENT OF ANTIBIOTIC ALLERGY

Alternatives for drug-allergic patients

Three alternative approaches are available to provide acceptable pharmacotherapy for infection in antibiotic-allergic patients (Figure 210.2). The physician may choose to use an unrelated antibiotic, or potentially cross-reactive alternative, or to readminister the implicated antibiotic after an induction of drug tolerance procedure, also commonly known as drug desensitization. A structurally unrelated antibiotic is usually chosen if the trade-offs of safety, efficacy, and cost are acceptable. This often occurs in the treatment of uncomplicated outpatient infections. If there is no acceptable alternative to the offending drug class, a potentially cross-reacting member of the same antibiotic family

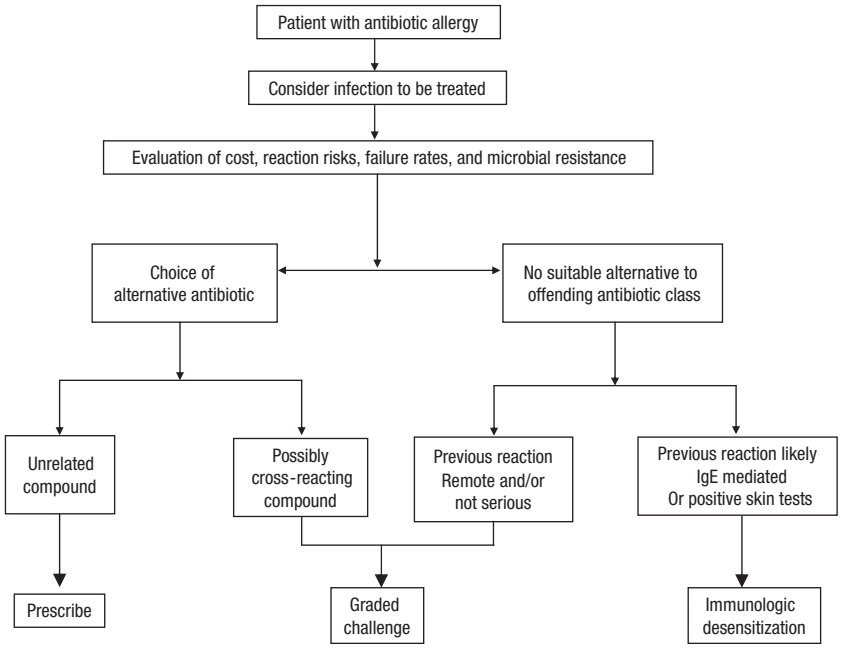

Figure 210.2 An approach to treating patients with antibiotic allergy.

may be administered using rapid dose escalation under careful observation. If a reaction occurs during graded challenge, then an induction of drug tolerance protocol is warranted. Classical induction of drug tolerance is applied only for IgE-dependent allergy in patients with demonstrable or presumed IgE antibody responses. Induction of drug challenge protocols have been used for non-IgE-mediated reactions; however, neither the effectiveness of the procedure nor a clear mechanism of action has been demonstrated. The procedure aims to induce a temporary state of drug tolerance.

Induction of drug tolerance procedures usually start at 1/10 000 of the full dose with a 2- to 2.5-fold dose increment every 30 to 60 minutes. The procedure entails risk of acute allergic reactions, which occur in mild form in 30% to 80% of penicillin-allergic patients undergoing desensitization. Reactions are generally confined to local and mild systemic reactions during the procedure and, occasionally, late-occurring reactions during therapy, including urticaria or serum sickness and hemolytic anemia if prolonged high-dose therapy is used. The protocol should usually be performed in a hospital setting where experienced personnel and emergency treatment are available. Induction of drug tolerance is an active and reversible process dependent on the continuous presence of the drug. After drug discontinuation, the tolerized state dissipates over days to weeks, and the induction of tolerance procedure would need to be repeated for subsequent treatment courses. Both oral and parenteral routes can be used to initiate drug tolerance, and both appear equally effective in inducing clinical tolerance. The oral approach is arguably safer, although not always feasible.

A variety of protocols have been used for reintroducing β-lactams, trimethoprim–sulfamethoxazole, vancomycin, and other antimicrobials. Tables 210.4 and 210.5 show illustrative published protocols for penicillin.

Management of β-lactam allergy

β-Lactam antibiotics are the most commonly prescribed class of antibiotics and the most frequent cause of antibiotic allergy. It is the only group of antibiotics for which skin tests have been validated. This group includes penicillins, cephalosporins, carbapenems, and monobactams, all of which share a β-lactam ring but otherwise vary in nuclear structure and side chains.

Table 210.4 Oral densensitization protocol

Step[a]	Phenoxymethyl penicillin (U/mL)	Amount (mL)	Dose (U)	Cumulative dosage (U)
1	1 000	0.1	100	100

If skin testing reagents are available, then therapy may be dispensed according to the result of skin tests. When reagents or consultants are not available, an approach is outlined in Figure 210.3. Patients with histories of a reaction to a β-lactam class other than penicillin should first be skin tested with the benzylpenicillin reagents and, if negative, with the diluted β-lactam chosen for use.

Cross-reactivity among β-lactam antibiotics

Cross-reactivity within the penicillin class is virtually complete. A patient who is allergic to any penicillin is likely to react to all penicillins. However, some data suggest that there are patients that are selectively allergic to amoxicillin or ampicillin while tolerating other penicillins. Immunologic cross-reactivity between cephalosporins and penicillins is readily demonstrated in vitro and by skin testing, yet multiple studies have shown that most patients with penicillin IgE responses can be safely treated with cephalosporins, especially those of third and fourth generation. Still, penicillin allergy conveys an odds ratio of 4.8 for acute reactions to first-generation cephalosporin in a recent meta-analysis, and in one series a majority of cases of fatal anaphylactic reactions to cephalosporins involved penicillin-allergic patients. Because of this, administration of cephalosporins to penicillin-allergic patients should be undertaken cautiously, especially for patients with previous life-threatening reactions to β-lactam antibiotics of any class.

Penicillin-allergic patients can be given the monobactam aztreonam with little risk because

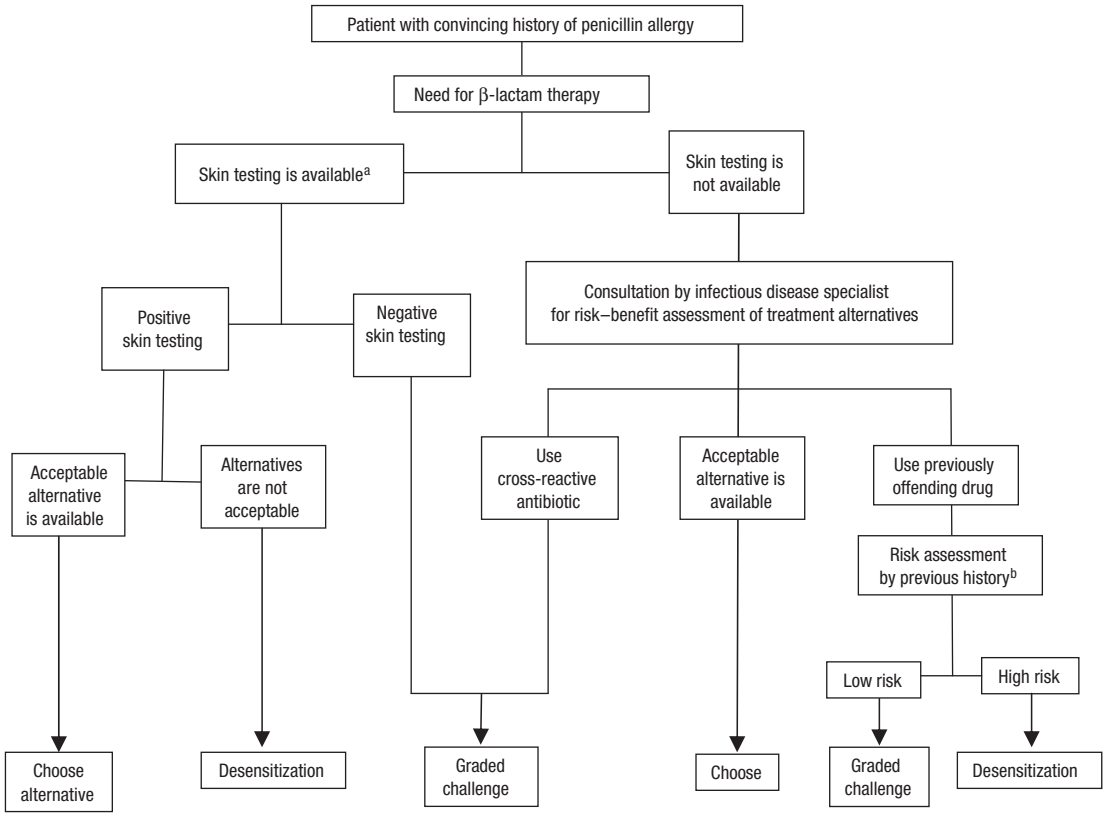

Figure 210.3 Diagnostic evaluation of patients with histories of penicillin allergy.
[a] Intradermal skin tests should include penicilloyl–polylysine (Pre-Pen) as a major determinant analog, plus one or more minor determinants (especially benzylpenicillin, benzylpenicilloate); the previously offending antibiotic if known and/or the currently desired antibiotic choice may be usefully included, especially in evaluating non-penicillin β-lactams.
[b] Risk assessment by previous history: High risk: Histories of bronchospasm, angioedema, hypotension, shock that occurred within 30 minutes of penicillin administration in the last year. Low risk: History of isolated urticaria or maculopapular rash occurring after days of treatment remotely >5 years in the past.

clinically significant cross-reactivity between penicillin and monobactams has not been demonstrated. In contrast, cross-reactions between aztreonam and ceftazidime have been reported, presumably due to identical side chains. The carbapenem antibiotics (imipenem, meropenem, and ertapenem) will induce positive skin tests in about half of penicillin-allergic patients. However, a clinical report from Europe found that 100% of 110 patients with positive penicillin skin tests tolerated imipenem. A more recent study found a cross-reactivity rate of 0.8% between penicillin and imipenem in 124 children. These data suggest that cautious cross-treatment may be reasonably attempted.

Sulfonamide antimicrobials (sulfamethoxazole, sulfadiazine, sulfisoxazole, and sulfacetamide) are extensively cross-reactive and also cross-react with dapsone. Sulfonamide antimicrobial agents differ from other sulfonamide-containing medications by having an aromatic amine group at the N4 position and a substituted ring at the N1 position that are not found in nonantibiotic sulfonamide-containing drugs. Patients allergic to sulfonamide antibiotics generally tolerate thiazide diuretics, oral hypoglycemic agents, and other SO_2-containing drugs and vice versa.

Other antibiotics

Immunologic reactions to quinolones and macrolides are very rare. These antibiotics mostly evoke maculopapular eruptions and

occasionally urticaria and angioedema (Table 210.3). As there are no validated skin or in vitro tests, drug provocation tests are the only available diagnostic methods for these classes of antibiotics.

Vancomycin is associated with two main types of hypersensitivity reactions, namely a nonallergic hypersensitivity reaction known as "red man syndrome" and anaphylaxis. Skin testing with vancomycin at $\leq$100 μg/mL is diagnostic for the presence of IgE antibodies that can be elicted by multiple courses of therapy.

Topical antibiotics such as bacitracin and neomycin usually cause delayed-type skin reactions. Although immediate-type reactions are rarely reported, repeated usage of bacitracin has been associated with near fatal anaphylaxis in a few cases. Hypersensitivity reactions to metronidazole are infrequently reported. Fixed drug eruptions and delayed-type skin reactions are the most common clinical presentations.

The general approach to antibiotic allergy as depicted in Figure 210.1 is also useful for management of adverse reactions to non-β-lactam antibiotics.

Multiple antibiotic allergy syndromes

Some patients show a marked propensity to react to several chemically unrelated antibiotics and sometimes nonantibiotic drugs. This condition has been termed the multiple drug allergy syndrome (MDAS). In most cases, MDAS presents clinically as acute urticaria +/− angioedema after ingestion of multiple doses of offending drugs. However, other variants including non-urticarial rashes, including SJS, anaphylaxis, serum sickness-like reactions, and immune cytopenias, have also been described. Mechanisms underlying multiple drug reactivity are still unclear. Published studies have suggested a high propensity to MDAS among patients with a history of allergy to β-lactams or any other antimicrobial drug. Whether MDAS results from a facilitated ability to make immune responses to drug haptens or an increased vulnerability to drug-induced immunopathology has yet to be determined. Some cases of MDAS are "pseudoallergic" and reflect classically conditioned responses that can readily be misinterpreted as anaphylaxis.

Clinical management of MDAS is similar to that of patients with single antibiotic allergy. Avoidance of unnecessary use of drugs should be the first step. Preferential use of low-risk antibiotics such as macrolides and quinolones may be helpful. If validated skin or in vitro tests are available, they can be helpful in permitting readministration of previously implicated drugs, especially β-lactams.

CONCLUSION

Patients relating a history of immune or nonimmune reactions to antibiotics are not rare in medical practice. As history alone has low diagnostic value, it is desirable that the history-positive patients should be evaluated by diagnostic tests when validated or by drug provocation tests when the index of suspicion is low. Although alternative antimicrobials can often be identified, they can have higher costs and treatment failures or greater toxicity. For the truly drug-allergic patient, management approaches include cautious administration of cross-reactive antimicrobials from the same class or drug desensitization. When approached systematically, almost all antibiotic-sensitive patients can be safely and effectively treated.

211. Antimicrobial agent tables

Jomy George and Rosalie Pepe

INTRODUCTION

The following tables of antimicrobial agents are organized as follows:

Table 211.1: Antibacterial Agents
Table 211.2: Antimycobacterial Agents
Table 211.3: Antifungal Agents
Table 211.4: Antiviral Agents
Table 211.5: Antiparasitic Agents

The listings are alphabetical by generic name, with the corresponding brand name provided; available data are included for dosage, cost, change in absorption with food, pregnancy class, dosage adjustment for renal failure and dialysis, and major toxicities.

Some agents no longer available in the United States are available elsewhere and are listed in generic form only.

Clinical Infectious Disease, Second Edition ed. David Schlossberg. Published by Cambridge University Press.

Table 211.1 Antibacterial agents

Name		Usual dose		Cost (AWP unit price)[a]	Change in absorption with food
Generic	**Brand**	**Adult**	**Child**		
Amikacin[c]	Amikin	15 mg/kg/d; divide q8–12h IV 10–40 mg IT q24h	15 mg/kg/d; divide q8–12h	250 mg/mL injection; 4 mL vial = $4.05	n.a.
Amoxicillin	Amoxil	0.25–0.5 g PO q8h or 875 mg PO q12h or 1000 mg PO q12h (*Helicobacter pylori*)	6.6–13.3 mg/kg PO q8h (neonate: 0–7 d, 25 mg/kg q12h; 1–4 wk 25 mg/kg q8h)	250 mg capsule: $0.25 500 mg capsule: $0.44 875 mg tablet: $0.87 400 mg/5 mL (50 mL) oral susp: $4.85	Decreased
Amoxicillin–clavulanate	Augmentin	0.25–0.5 g PO q8h 875 mg PO q12h 2000 mg PO q12h XR tablets	6.6–13.3 mg/kg PO q8h	250/150 mg tablet: $4.11 500/125 mg tablet: $3.78 875/125 mg tablet: $5.05 XR 1000/62.5 mg tablet: $3.87 400 mg/5 mL (50 mL) oral susp: $68.93	Decreased
Ampicillin	Ampen, Omnipen	0.5–1 g PO q8h; 1–2 g IV q4–6h	12.5–25 mg/kg PO q8h 6.25–25 mg/kg IV q8h	250 mg capsule: $0.22 500 mg capsule: $0.40 250 mg IV vial: $3.98 1000 mg IV vial: $8.20	Decreased
Ampicillin–sulbactam	Unasyn	1.5–3 g IV q6h	25–50 mg/kg IV q6h	1.5 g IV vial: $7.73 3 g IV vial: $14.60	n.a.
Azithromycin	Zithromax	5 g day 1; 0.25 g days 2–5 PO	–[b]	250 mg tablet: $7.78 500 mg tablet: $21.21 500 mg IV vial: $7.20 100 mg/5 mL (15 mL) oral susp: $32.93	Decreased
Azlocillin		2–4 g IV q4–6h	75 mg/kg IV q6h	Data not available	n.a.
Aztreonam	Azactam	1–2 g IV q6–8h	30–50 mg/kg q6–12h (n.a.)	1 g IV vial: $39.50 2 g vial: $80.34	n.a.
Bacampicillin		0.4–0.8 g PO q12h	12.5–25 mg/kg PO q12h	Data not available	None
Carbenicillin indanyl sodium		1–2 0.382-g tabs PO q6h	7.5–12.5 mg/kg PO q6h	Data not available	Increased
Cefaclor	Ceclor	0.25–0.5 PO q8h	20–40 mg/kg/d; divide q8h PO	250 mg capsule: $1.98 500 mg capsule: $3.89	Decreased
Cefadroxil	Duricef	0.5–1 g PO q12–24h	30 mg/kg/d; divide q12h PO	500 mg capsule: $3.72	Decreased
Cefamandole		0.5–2 g IV q4–8h	50–150 mg/kg/d; divide q4–8h IV	Data not available	n.a.
Cefazolin	Ancef, Kefzol	0.5–2 g IV q8h	25–100 mg/kg/d; divide q6–8h IV	500 mg IV vial: $1.30 1 g IV vial: $2.61	n.a.

Pregnancy class[a]	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis		Major toxicity
	>50	10–50	≤10	HD	PD	
D	q8–12h	q12–48h	>48h	2.5–3.75 mg/kg pHD	2.5 mg/kg/d IV or 3–4 mg/2 L dialysate removed	Renal toxicity, vestibular or auditory toxicity, CNS reactions, neuromuscular blockade (rare)
B	q8h	q8–12h	q16–24h	0.25–0.5 g	0.25 g q12h	Allergic reactions (rare: anaphylactic), rash, diarrhea, nausea, vomiting
B	q8h	q12h	q12–24h	0.25 g PO	–[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting, cholestatic hepatitis
B	q4–6h	q8h	q12–24h	0.5–2 g	0.25 g PO q12h or 1–4 g IV q24h	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
B	q6–8h	q8–12h	q24h	2 g ampicillin pHD	–[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
B	Usual	Usual	Usual	–[b]	–[b]	GI disturbance, headache
B	q4–6h	q8h	q12h	3 g pHD	–[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
B	q6–8h	q12–18h	q24h	18 first dose (60–250 mg) pHD	Usual dose (1–2 g) then usual dose at usual intervals	Rash, diarrhea, nausea, vomiting, elevated AST/ALT
B	q12h	q12h	–[b]	–[b]	–[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
B	–[b]	–[b]	–[b]	–[b]	–[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
B	q8h	q8h	q8h	0.25–0.5 g	–[b]	Allergic reactions, GI disturbance, arthritis, serum sickness
B	q12–24h	0.5 g q12–24h	0.5 g q36h	0.5–1 g	–[b]	Allergic reactions, GI disturbance
B	q4–8h	q8h	0.5–1 g q12h	0.5–1 g	–[b]	Thrombophlebitis with IV infusion, allergic reactions, GI disturbance
B	q8h	0.5–1 g q8–12h	0.5–1 g q24h	0.25–0.5 g	–[b]	Allergic reactions, GI disturbance, diarrhea

Table 211.1 *(continued)*

Name		Usual dose		Cost (AWP unit price)[a]	Change in absorption with food
Generic	**Brand**	**Adult**	**Child**		
Cefdinir	Omnicef	300 mg PO q12h	14 mg/kg/d PO qd divide q12–24h	300 mg capsule: $5.10 250 mg/5 mL (60 mL): $51.01	Minimal decrease
Cefditoren	Spectracef	400 mg PO BID	400 mg PO BID	400 mg capsule: $14.74	Increased
Cefepime	Maxipime	0.5–2 g IV q12h	50 mg/kg IV q8h (n.a.)	1 g IV vial: $6.96 2 g IV vial: 11.86	n.a.
Cefixime	Suprax	0.4 g PO q24h	8 mg/kg/d; divide PO q24h	400 mg tablet: $20.16	Decreased
Cefmetazole		2 g IV q6–12h	–[b]	Data not available	n.a.
Cefonicid		0.5–2 g IV q24h	–[b]	Data not available	n.a.
Cefoperazone		1–2 g IV q6–12h	25–100 mg/kg IV q12h (n.a.)	Data not available	n.a.
Cefotaxime	Claforan	0.5–2 g IV q8–12h; 3 g q6h for CNS	50–200 mg/kg/d; divide IV q4–8h (neonate: 0–7 d, 50 mg/kg q12h; 1–4 wk: 50 mg/kg q6–8h)	500 mg IV vial: $3.65 1 g IV vial: $4.36 2 g IV vial: $8.54	n.a.
Cefotetan	Cefotan	1–2 g IV q12h	40–60 mg/kg/d; divide IV q12h (n.a.)	1 g IV vial: $17.58 2 g IV vial: $25.14	n.a.
Cefoxitin	Mefoxin	1–2 g IV q6–8h	80–160 mg/kg/d; divide IV q4–8h	1 g IV vial: $11.22 2 g IV vial: $22.50	n.a.
Cefpodoxime	Vantin	0.1–0.4 g PO q12h	5 mg/kg PO q12h	100 mg tablet: $6.73 200 mg tablet: $8.45	Increased
Cefprozil	Cefzil	0.25–0.5 g PO q12–24h	15 mg/kg PO q12h	250 mg tablet: $4.37 500 mg tablet: $9.04	No effect
Ceftaroline	Teflaro	600 mg IV q12h	–[b]	600 mg IV: $59.98	n.a.
Ceftazidime	Fortaz, Tazicef, Tazidime	1–2 g IV q8–12h	25–50 mg/kg IV q8h	1 g IV vial: $12.90 2 g IV vial: $18.59	n.a.
Ceftibuten	Cedax	400 mg PO q12h	3–6 mg/kg PO q8h	400 mg capsule: $19.19	Increased
Ceftizoxime	Cefizox	1–3 g IV q6–8h	33–50 mg/kg IV q6–8h	No data available	n.a.
Ceftriaxone	Rocephin	0.5–2 g IV q12–24h (neonate: 0–7 d, 50 mg/kg q24h; 1–4 wk, 50–75 mg/kg q24h)	50–100 mg/kg/d; divide IV q12–24h	250 mg IV vial: $1.50 500 mg IV vial: $1.50 1 g IV vial: $2.64 2 g IV vial: $5.28	n.a.

Pregnancy class[a]	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis		Major toxicity
	>50	10–50	≤10	HD	PD	
B	Usual	300 mg q24h	300 mg q24h	Not defined	Not defined	Anaphylaxis, TEN, erythema multiforme, neutropenia
B	400 mg PO BID	200 mg PO BID	200 mg PO qd	None	–[b]	Anaphylaxis, leukopenia, neutropenia, thrombocytopenia
B	0.5–2 g IV q12h	q24h	0.25–0.5 g q24h	Dose pHD	0.5–2 g q48h	Nausea, diarrhea, vomiting, rash, phlebitis
B	q24h	0.3 g q24h	q48h	None	–[b]	Thrombophlebitis, allergic reactions, GI disturbance
B	q6–12h	q16–24h	q48h	–[b]	–[b]	Thrombophlebitis, allergic reactions, GI disturbance
B	q24h	4–15 mg/kg q24–48h	3–15 mg/kg q3–5 days	None	–[b]	Allergic reactions, GI disturbance, hypoprothrombinemia or hemorrhage
B	q6–12h	q6–12h	q6–12h	Dose after HD	–[b]	Thrombophlebitis, allergic reactions, GI disturbance
B	q8–12h	q12–24h	0.5 g q24–48h	0.5–2 g	–[b]	Thrombophlebitis, allergic reactions, GI disturbance
B	q12h	q24h	q48h	25% dose nonHD days, 50% HD	–[b]	Thrombophlebitis, allergic reactions, GI disturbance, hypoprothrombinemia, hemorrhage
B	q6–8h	q12–24h	0.5–1 g q12–24h	1–2 g	–[b]	Thrombophlebitis, allergic reactions, GI disturbance
B	q12h	q24h	q24h	Dose 3 × wk	–[b]	Allergic reactions, GI disturbance
B	q12–24h	50% dose q12–24h	50% dose q12–24h	–[b]	–[b]	Allergic reactions, GI disturbance
B	q12h	300-400 mg q12h	200 mg q12h	None	–[b]	Allergic reactions, diarrhea, nausea, direct Coombs seroconversion
B	q8–12h	q12–24h	q24–48h	1 g load then 1 g pHD	0.5 g IV q24h or 250 mg/2 L dialysate	Thrombophlebitis, allergic reactions, GI disturbance
B	for CrCl 30: 400 mg q12–24h PO 12; for CrCl 5: 29–200 mg PO qd	for CrCl 30: 400 mg q24h PO 12; for CrCl 5: 29–200 mg PO qd	100 mg q24h	400 mg pHD		Seizures, anaphylaxis, TEN, Stevens–Johnson syndrome, erythema multiforme
B	q6–8h	0.25–1 g q12h	0.5 g q24h	Dose pHD	3 g q48h	Thrombophlebitis, allergic reactions, GI disturbance
B	q12–24h	q12–24h	q12–24h	None	–[b]	Thrombophlebitis, allergic reactions, GI disturbance, cholelithiasis

Table 211.1 *(continued)*

Name		Usual dose		Cost (AWP unit price)*	Change in absorption with food
Generic	**Brand**	**Adult**	**Child**		
Cefuroxime	Zinacef, Kefurox	0.75–1.5 g IV q8h	50–100 mg/kg/d divide IV q6–8h	750 mg IV vial: $3.67 1.5 g IV vial: $13.12	n.a.
Cefuroxime axetil	Ceftin	0.125–0.5 g PO q12h	0.125–0.25 g PO q12h	250 mg tablet: $4.39 500 mg tablet: $8.01	Decreased
Cephalexin	Keflex, Biocef, Keftab	0.25–1 g PO q6h	25–100 mg/kg/d; divide PO q6h	250 mg capsule: $0.69 500 mg capsule: $1.37 750 mg capsule: $7.69	Unchanged
Cephalothin		0.5–2 g IV q4–6h	80–160 mg/kg/d; divide IV q6h	Data not available	n.a.
Cephapirin		0.5–2 g IV q4–6h	40–80 mg/kg/d divide IV q6h	Data not available	n.a.
Cephradine		0.25–1 g PO q6h 0.5–2 g IV q4–6h	25–100 mg/kg/d; divide PO q6–12h 50–100 mg/kg divide IV q6h	Data not available	Decreased
Chloramphenicol	Chloromycetin	0.25–0.75 g PO q6h 0.25–1 g IV q6h	50–100 mg/kg/d; divide q6h PO, IV	PO: data not available 1 g IV vial: $17.00	Vitamins may increase absorption
Cinoxacin		0.25 g q6h, 0.5 g PO q12h	N.R.	Data not available	Delayed absorption and lower mean peak serum levels
Ciprofloxacin	Cipro	0.25–0.75 g PO q12h 0.2–0.4 g IV q12h	N.R.	250 mg tablet: $0.31 500 mg tablet: $0.36 750 mg tablet: $0.40	Decreased
Clarithromycin	Biaxin	0.25–0.5 g PO q12h	7.5 mg/kg q12h (n.a.)	250 mg tablet: $4.50 500 mg tablet: $4.52	Increased or unchanged
Clindamycin	Cleocin	0.15–0.3 g PO q6h 0.3–0.9 g IV q6–8h	8–25 mg/kg/d; divide PO q6–8h 15–40 mg/kg/d; divide IV q6–8h (newborn: 0–7 d, 15 mg/kg/d q6–8h; 1–4 wk, 15–20 mg/kg/d q6–8h)	150 mg capsule: $1.19 300 mg IV bag: $0.11 600 mg IV bag: $0.16 900 mg IV bag: $0.19	Unchanged
Cloxacillin		0.5–1 g PO q6h	12.5–25 mg/kg PO q6h	Data not available	Decreased
Colistin		5–15 mg/kg/d PO q8h 2.5–5 mg/kg/d IV q6–12h	5–15 mg/kg/d; divide PO q8h 2.5–5 mg/kg/d; divide IV q6–12h	150 mg IV vial: $57.00	Not significantly absorbed orally
Dapsone		0.05–0.1 g PO q24h	1–2 mg/kg/d; divide q24h	25 mg tablet: $1.06 100 mg tablet: $1.30	No effect
Daptomycin	Cubicin	4–6 mg/kg IV q24h	Not defined	500 mg IV vial: $382.44	n.a.
Dicloxacillin	Dynapen	0.25–0.5 g PO q6h	3.125–6.25 mg/kg PO q6h	250 mg capsule: $0.66 500 mg capsule: $1.12	Decreased

Pregnancy class[a]	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis		Major toxicity
	>50	10–50	≤10	HD	PD	
B	q8h	q8–12h	0.75 g q24h	0.75 g pHD	15 mg/kg pPD	Thrombophlebitis, allergic reactions, GI disturbance
B	q12h	q12h	0.25 g q24h	–[b]	–[b]	Allergic reactions, GI disturbance
B	q6h	q8–12h	q24–48h	0.25–1 g	–[b]	Allergic reactions, GI disturbance
B	q4–6h	1–1.5 g q6h	0.5 g q8h	0.5–2 g	Add up to 6 mg/kg to dialysate	Thrombophlebitis with IV infusion, allergic reactions, GI disturbance
B	q4–6h	q8h	q12h	7.5–15 mg/kg pHD then q12h	–[b]	Thrombophlebitis, allergic reactions, GI disturbance
B	q6h	0.5 g q6h	0.25 g q12h	0.25 g before HD, then 12, 36, and 48 h pHD	0.5 g q6h	Allergic reactions, GI disturbance
C	Usual	Usual	Usual	Dose pHD	Usual	Blood dyscrasias, gray baby syndrome, GI disturbance
C	q6h	0.25 g q12–24h	N.R.	–[b]	–[b]	Nausea, vomiting, dizziness, headache, tremors, confusion
C	q12h	0.25–0.5 g PO q12h, IV q12–24h	0.25–0.5 g PO q18h, IV q18–24h	0.25–0.5 g q24h, pHD on HD days	0.25–0.5 g q24h	Nausea, vomiting, dizziness, headache, tremors, confusion
B	q12h	q12–24h	q24h	–[b]	–[b]	GI disturbance, abnormal taste, headache
B	Usual	Usual	Usual	Usual	Usual	Diarrhea, including pseudomembranous colitis, allergic reactions
B	q6h	q6h	q6h	Usual	Usual	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
Not established	q6–12h	2.5 mg/kg/d q12–24h	1.5 mg/kg q36h	–[b]	–[b]	Nephrotoxicity, CNS side effects including confusion, coma, seizures
C	q24h	q24h	q24h	–[b]	–[b]	Rash, headache, GI irritation, infectious mono-like syndrome
B	4–6 mg/kg q24h	4–6 mg/kg q48h	4–6 mg/kg q48h	4–6 mg/kg q48h. Administer after dialysis session on dialysis days	4–6 mg/kg q48h	Arrhythmias, hypersensitivity rxn, anaphlyaxis, thrombocytopenia, myopathy
Not established	q6h	q6h	q6h	Usual	Usual	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting

Table 211.1 *(continued)*

Name		Usual dose		Cost (AWP unit price)[a]	Change in absorption with food
Generic	**Brand**	**Adult**	**Child**		
Doripenem	Doribax	500 mg IV q8h	—[b]	250 mg IV vial: $25.30 500 mg IV vial: $45.99	n.a.
Doxycycline	Vibramycin	0.1 g PO, IV q12h	2.2 mg/kg PO, IV q12–24h	100 mg tablet: $4.06 100 mg IV vial: $18.02	Decreased with milk, antacids
Enoxacin		0.4 g PO, IV q12h	N.R.	Data not available	Decreased
Ertapenem	Invanz	1 g IM/IV qd	30 mg/kg/d IM/IV BID	1 g vial: $84.89	n.a.
Erythromycin base		0.25–0.5 g PO q6h	30–50 mg/kg/d; divide q6h	Data not available	Decreased
Erythromycin estolate		0.25–0.5 g PO q6h	3–50 mg/kg/d; divide q6h	Data not available	Decreased
Erythromycin ethyl succinate	EES, EryPed	0.4 g PO q8h	30–50 mg/kg/d divide PO q8h	400 mg tablet: $3.26	Increased
Erythromycin lactobionate		0.5–1 g IV q6h	15–20 mg/kg/d; divide IV q6h	Data not available	n.a.
Fidaxomicin	Dificid	200 PO BID	—[b]	200 mg tablet: $177.46	None
Gatifloxacin		400 mg daily PO or IV	—[b]		None
Gentamicin[c]	Garamycin	3–5 mg/kg/d; divide IV q8h 4–8 mg/d IT	3–7.5 mg/kg/d; divide IV q8h (newborn: 0–7 d, 2.5 mg/kg q12h; 1–4 wk, 7.5 mg/kg/d q8h)	100 mg/100 mL IV bag: $0.04	n.a.
Grepafloxacin		400 mg or 600 mg daily	—[b]	Data not available	No change
Imipenem	Primaxin	0.5–1 g IV q6h	15–25 mg/kg IV q6h (n.a.) (neonate: 0–7 d, 25 mg/kg q12h; 1–4 wk, 25 mg/kg q8h)	250 mg IV vial: $11.76 500 mg IV vial: $23.52	n.a.
Kanamycin[c]	Kantrex	15 mg/kg/d; divide IV q8–12h	15 mg/kg/d; divide IV q8–12h (newborn: 0–7 d, 15–20 mg/kg/d q12h; 1–4 wk, 15 mg/kg/d q8–12h)	1 g vial: $19.32	n.a.
Levofloxacin	Levaquin	0.25–0.75 g/d PO or IV	N.R.	250 mg tablet: $16.81 500 mg tablet: $19.26 750 mg tablet: $36.07 250 mg IV bag: $0.15 500 mg IV bag: $0.12	Unchanged
Lincomycin	Lincocin	0.5 g PO q6–8h 0.6–1 g IV q8–12h	30–60 mg/kg/d; divide PO q6–8h 10–20 mg/kg/d; divide IV q6h	PO: data not available 300 mg/mL (10 mL) vial: $9.48	Decreased

Pregnancy class[a]	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis		Major toxicity
	>50	10–50	≤10	HD	PD	
B	q8h	250 mg q8h	250 mg q12h	–[b]	–[b]	Anaphylaxis, hypersensitivity, GI disturbance
D	q12h	q12h	q12h	Usual	Usual	GI disturbance, photosensitivity reactions, hepatic toxicity, esophageal ulcers
C	q12h	0.1–0.2 g q12h	0.1–0.2 g q12h	–[b]	–[b]	Nausea, vomiting, dizziness, headache, tremors, confusion
B	1 g IM/IV qd	CrCl ≤30: 500 mg qd	CrCl ≤30: 500 mg qd	30% of daily dose should be supplemented pHD	–[b]	Thrombocytopenia, increased LFTs, diarrhea, allergic reactions
B	q6h	q6h	q6h	Usual	Usual	GI disturbance; rare: allergic reactions, hepatic dysfunction, hearing loss
B	Usual	Usual	Usual	No change	No change	Cholestatic hepatitis, hearing loss or tinnitus, GI disturbance, hypersensitivity reactions
B	Usual	Usual	Usual	Usual	Usual	GI disturbance; rare: allergic reactions, hepatic dysfunction
B	Usual	Usual	Usual	Usual	Usual	GI disturbance; rare: allergic reactions, hepatic dysfunction, hearing loss
B	Usual dose	Usual dose	Usual dose	None	None	Nausea, vomiting, hypersensitivity reaction
	Usual dose	400 mg ×1 then 50% q24h	–[b]	–[b]	–[b]	Hyperglycemia, hypoglycemia, QT prolongation, tendon rupture
C	q8–12h	q12–48h	>48 h	1–1.7 mg/kg pHD	1 mg/2 L dialysate removed	Renal toxicity, vestibular and auditory toxicity, CNS reactions, neuromuscular blockade (rare)

Abbreviations: CrCl = creatinine clearance (mL/min); HD = hemodialysis; PD = peritoneal dialysis; CNS = central nervous system; GI = gastrointestinal; TEN = toxic epidermal necrolysis; rxn = reaction; ICP = intracranial pressure; P = post; LFTs = liver function tests.

[a] Food and Drug Administration pregnancy categories: A = adequate studies in pregnant women, no risk; B = animal studies no risk, human studies inadequate, benefit may outweigh risk; X = fetal abnormalities in humans, risk exceeds benefit.

[b] Insufficient information available to make a recommendation.

[c] Aminoglycoside dosing may be modified after obtaining serum levels. The generally desired peak and trough concentrations are as follows: for gentamicin and trough ≤5–10 μg/mL. With once-daily administration of aminoglycosides, doses are 5–7 mg/kg q24h for gentamicin and tobramycin, 6.5 mg/kg for netilmicin trough ≤1 μg/mL; for netilmicin, peak 22–30 μg/mL, trough ≤1 μg/mL; for amikacin, kanamycin and streptomycin, peak 56–64 μg/mL, trough ≤1 μg/mL.

Not established	Usual	–[b]	–[b]	–[b]	–[b]	Abdominal pain, vomiting, diarrhea, headache, pruritus, rash
C	Usual	–[b]	–[b]	–[b]	–[b]	Blurred vision, GI effects, pruritus; rare: cardiomyopathy

Table 211.5 *(continued)*

Name		Usual dose			
Generic	**Brand**	**Adult**	**Child**	**Cost (AWP unit price)***	**Change in absorption with food**
Iodoquinol	Yodoxin, Diquinol	650 mg PO TID	30–40 mg/kg/d; divide PO TID	650 mg tablet: $1.47	Minimally absorbed
Ivermectin	Stromectol	200 μg/kg	–[b]	3 mg tablet: $5.58	Decreased
Mebendazole	Vermox	100 mg PO BID depending on infection being treated	Same as adults	Data not available	Minimally absorbed
Mefloquine	Lariam	250 mg/wk (prophylaxis) 1250 mg ×1 (treatment)	25 mg/kg PO qwk (prophylaxis)	250 mg tablet: $10.59	Increased
Meglumine antimonate[c]	Glucantine	20 mg/kg IV ×2 d (850 mg/d limit)	–[b]	Data not available	n/a
Melarsoprol B[d]	Mel B, Arsobal	1.2 mg/kg IV TID × 3 d; repeat qwk ×2 wk	–[b]	Data not available	n/a
Niclosamide	Niclocide	2 g PO qd	0.5–1.5 g/d PO	Data not available	Not absorbed
Nifurtimox[d]	Lampit	3 mg/kg PO TID ×3 mo	–[b]	Data not available	–[b]
Niridazole[c]	Ambilhar	–[b]	–[b]	Data not available	–[b]
Oxamniquine[c]	Vansil	12–60 mg/kg qd or divide BID	20–60 mg/kg divided BID	Data not available	Decreased
Paromomycin	Humatin	25–35 mg/kg PO divided TID 2–3 g qd divided QID in AIDS	–[b]	250 mg capsule: $5.67	Not absorbed
Pentamidine	Pentam, Nebupent	3–4 mg/kg/d IV 300 mg aerosolized qmo	3–4 mg/kg/d IV	300 mg IV: $118.50 300 mg inhalation: $118.50	n/a
Piperazine citrate[c]	Antepar	2–3.5 g/d PO	65–75 mg/kg PO qd	Data not available	–[b]
Praziquantel	Biltricide	5–25 mg/kg ×1 (intestinal cestodiasis) 50–75 mg/kg/d, divided TID (other infections)	Not shown to be safe for children <4 yr	600 mg tablet: $17.27	Increased
Primaquine phosphate		26.3 mg/d PO ×14 d 29 mg PO qwk × 8 wk	0.5 mg/kg/d PO 1.5 mg/kg PO qwk	26.3 mg tablet: $1.78	–[b]
Proguanil HCl and atovaquone	Malarone	400/1000 mg PO qd (treatment) 100/250 mg PO daily 1–2 d before entering endemic area, during stay, and for 7 d after return (prophylaxis)	50/125–1000/400 mg PO qd (depending on weight) (treatment) 25/62.5–100/250 mg PO qd (depending on weight) (prophylaxis)	100 mg/250 mg tablet: $8.24 25 mg/62.5 mg tablet: $2.99	Increased
Pyrantel pamoate	Antiminth, Pin-X	11 mg/kg (max 1 g/d) PO	11 mg/kg/d PO; not recommended for children ≤2 yr	Data not available	–[b]
Pyrimethamine	Daraprim	25–75 mg/d PO	0.5–2 mg/kg PO, divide BID Contraindicated for children ≤2 yr	25 mg tablet: $14.14	–[b]

Pregnancy class[a]	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis		Major toxicity
	>50	10–50	≤10	HD	PD	
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Optic neuritis, peripheral neuropathy, anorexia, nausea, vomiting, diarrhea, skin reactions
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Fever, pruritus, headache, edema
B	Usual	–[b]	–[b]	–[b]	–[b]	Diarrhea, nausea, vomiting, abdominal pain, fever, headache, neutropenia, thrombocytopenia
C	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, dizziness, seizures, bradycardia, rash
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Bradycardia, hypotension, rashes, facial edema, injection site pain, pancreatitis, leukopenia, nephrotoxicity
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Fever, hypertension, abdominal pain, vomiting, arthralgia, encephalopathy, rash, hemolysis in patients with G6PD deficiency
B	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, abdominal discomfort, diarrhea, drowsiness, dizziness, headache
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, vomiting, abdominal pain, anorexia, weight loss, restlessness, insomnia, paresthesias, seizures, rash, neutropenia
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Seizures, hallucinations
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Dizziness, drowsiness, headache, nausea, vomiting, abdominal pain, orange-red discoloration of urine
Not established	Usual	Usual	Usual	–[b]	–[b]	Anorexia, nausea, vomiting, abdominal pain, diarrhea, malabsorption
C	Usual	–[b]	–[b]	–[b]	–[b]	Nephrotoxicity, hypotension, sterile abscess with IM injection, hypoglycemia or hyperglycemia, nausea, vomiting, abdominal pain, pancreatitis, hypocalcemia, cough and bronchospasm with inhalation
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, vomiting, diarrhea, abdominal cramps, headache, dizziness, rash, hemolytic anemia, ataxia
B	Usual dose	N.R.	N.R.	–[b]	–[b]	Transient dizziness, headache, drowiness, fatigue, seizures, CSF reaction syndrome with treatment of neurocysticercosis, abdominal pain, nausea, rash
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Hemolytic anemia in patients with G6PD deficiency, nausea, vomiting, abdominal cramps, headache, pruritus
C	Usual	N.R. in patients with CrCl ≤30 mL/min	N.R. in patients with CrCl ≤30 mL/min	N.R. in patients with CrCl ≤30 mL/min	N.R. in patients with CrCl ≤30 mL/min	Rare hematologic toxicity
C	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, vomiting, cramps, dizziness, drowsiness, headache
C	Usual	–[b]	–[b]	–[b]	–[b]	Bone marrow suppression with high doses, pulmonary eosinophilia, photosensitivity

Table 211.5 *(continued)*

Name		Usual dose			
Generic	**Brand**	**Adult**	**Child**	**Cost (AWP unit price)***	**Change in absorption with food**
Pyrimethamine + sulfadiazine	Fansidar	1 tab PO qwk (prophylaxis) 3 tabs PO ×1 (treatment)	½ tab PO 5–10 kg 1 tab 10–20 kg 1½ tab 21–30 kg 2 tabs 31–40 kg For children >2 yr	Data not available	–[b]
Quinacrine HCl[c]	Atabrine	100 mg TID PC ×5 d	6 mg/kg TID PC ×5 d (≤50 kg)	Data not available	–[b]
Quinidine gluconate		10 mg/kg load over 1–2 h, then 0.02 mg/kg/min ×72 h	Same as adult	800 mg (80 mg/mL) 10 mL IV: $21.56	Increased
Quinine sulfate	Legatrin Quinamm	325–650 g PO BID–TID	25–30 mg/kg/d PO; divide TID	325 mg capsule: $0.90	–[b]
Spiramycin[c]	Rovamycine	3 g/d PO	50–100 mg/kg once or 2× daily (depending on infection being treated)	Data not available	No effect
Stibogluconate	Pentostam	20 mg/kg IV qd × 20 d (not to exceed 850 mg)	–[b]	Data not available	n/a
Suramin[d]	Germanin	1 g IV qwk ×5 wk (100-mg test dose)	–[b]	Data not available	n/a
Thiabendazole	Mintezol	25 mg/kg PO BID (maximum 3 g/d)	22 mg/kg PO BID	Data not available	–[b]
Trimetrexate	Neutrexin	45 mg/m^2/d with leucovorin 20 mg/m^2 q6h; continue leucovorin at least 72 h after last dose	–[b]	Data not available	n/a

Abbreviations: CrCl = creatinine clearance mL/min; HD = hemodialysis; PD = peritoneal dialysis; AST = aspartate aminotransferase; N.R. = not recommended; PC = after meals; CSF = cerebrospinal fluid; n.a. = not approved; LFT = liver function test.

[a] Food and Drug Administration pregnancy categories: A = adequate studies in pregnant women, no risk; B = animal studies no risk, human studies D = evidence of human risk, benefit may outweigh risk; X = fetal abnormalities in humans, risk exceeds benefit.

[b] Insufficient information available to make a recommendation.

[c] Not available in the United States.

[d] Available from the Centers for Disease Control and Prevention drug service.

* 2013 Red Book Online ®; AWP = average wholesale price; unit price = per dose.

Pregnancy class[a]	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis		Major toxicity
	>50	10–50	≤10	HD	PD	
C	Usual	–[b]	–[b]	–[b]	–[b]	Leukopenia, hemolysis in patients with G6PD deficiency, rash and hypersensitivity reactions including Stevens–Johnson syndrome, hepatitis, pulmonary hypersensitivity reactions
C	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, vomiting, headache, dizziness, yellow discoloration of skin and urine, rash, fever, psychosis
C	Usual	–[b]	–[b]	–[b]	–[b]	Diarrhea, abdominal pain, hypersensitivity reactions, systemic lupus erythematosus-like syndrome, elevated AST, elevated ALT, jaundice, cardiac arrhythmias
X	Usual	–[b]	–[b]	–[b]	–[b]	Flushing, pruritus, rash, fever, tinnitus, headache, nausea, thrombocytopenia, hemolysis in patients with G6PD deficiency, hypoglycemia
C	Usual	–[b]	–[b]	–[b]	–[b]	QT interval prolongation, vasculitis, rash, diarrhea, increased LFTs
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Abdominal pain, nausea, vomiting, malaise, headache, elevated AST and ALT, nephrotoxicity, myalgia, arthralgia, fever, rash, cough
Not established	Usual	–[b]	–[b]	–[b]	–[b]	Nausea, vomiting, shock, loss of consciousness, death during administration; fever, rash, exfoliative dermatitis, paresthesia, photophobia, renal insufficiency, diarrhea
C	Usual	–[b]	–[b]	–[b]	–[b]	Anorexia, nausea, vomiting, dizziness
D	Usual	–[b]	–[b]	–[b]	–[b]	Neutropenia (must be given with leucovorin); rash; elevated AST and ALT; reversible peripheral neuropathy

ALT = alanine aminotransferase; GI = gastrointestinal; G6PD = glucose-6-phosphate dehydrogenase; AIDS = acquired immunodeficiency syndrome;

inadequate, or animal toxicity, human studies no risk; C = animal studies show toxicity, human studies inadequate but benefit may exceed risk;
